Because drug-induced neutropenia is the most common cause of acquired neutropenia, a careful inventory for drugs and toxins is warranted. Likewise, patients should be evaluated for potential precipitating malignant and inflammatory conditions. The time course of the neutropenia and infections can provide insight into the etiology (acute versus chronic, persistent versus cyclic, neonatal versus childhood versus adult onset). Attention should be paid to the skin, bones, appendages, and nails because abnormalities in these may point toward one of the congenital neutropenia syndromes. Evaluation of the complete blood count, peripheral blood smear, and vitamin B_{12} and folate levels should also be performed.

When the neutropenia is mild and associated with anemia and thrombocytopenia, the possibility of hypersplenism should be considered. Diagnosis can often be made by the finding of palpable splenomegaly. However, especially in obese patients, abdominal imaging may be used to evaluate spleen size. Abdominal ultrasound also allows the assessment of portal venous flow with Doppler studies. If splenic enlargement is confirmed, the etiology of the splenomegaly (Chapter 154) should be determined. The diagnosis of cyclic neutropenia formerly required demonstration of transient neutropenia through frequent blood counts over a course of 6 weeks but now can be established by sequencing of the elastase gene.

In other patients with chronic neutropenia without a history of infection, drug or toxin exposure, or B_{12} or folate deficiency, bone marrow examination should be performed to exclude myelodysplasia, with assessment of morphology, flow cytometry for the large granular lymphocyte syndrome, and cytogenetics. Once a normal marrow has been obtained, further bone marrow examination is not indicated in adults with chronic idiopathic neutropenia (Fig. 153-7).

TREATMENT

Management of the neutropenia patient is nuanced and depends on the etiology of the depressed count, its severity, and the presence or absence of fever.

Neutropenia After Chemotherapy

In *afebrile* adults with acquired neutropenia following chemotherapy, antibiotic prophylaxis with a quinolone (ciprofloxacin 500 mg orally twice a day, switched to 200 mg intravenously twice a day if the patient develops severe mucositis or intolerance to the oral formulation) or oral sulfamethoxazole/trimethoprim (1 double-strength tablet daily) can reduce all-cause mortality and is recommended along with antifungal prophylaxis (e.g., oral voriconazole 200 mg twice daily) in patients who are expected to have profound, protracted neutropenia (<100 neutrophils/μL for >7 days).[14] Trimethoprim-sulfamethoxazole is specifically recommended in patients at risk for *Pneumocystis jirovecii* pneumonia (Chapter 313), based on neutropenia in the setting of the equivalent of 20 mg or more of prednisone/day for 1 month or longer.

In afebrile neutropenia, the routine prophylactic administration of colony-stimulating factors does not appear to be beneficial,[A1] but many oncologic professional society guidelines recommend the use of prophylactic G-CSF in patients who are receiving chemotherapy and who have a 20% or greater risk for developing febrile neutropenia based on their age, comorbid illnesses, disease characteristics, and the myelotoxicity of the chemotherapy regimen. G-CSF is also recommended during hematopoietic stem cell transplantation (Chapter 163), for patients receiving chemotherapy for non-Hodgkin lymphoma (Chapter 171) or dose-dense chemotherapy, and for patients with a history of febrile neutropenia receiving further chemotherapy. In afebrile neutropenia, granulocyte transfusions may reduce the risk of infection but do not reduce mortality.[A2]

The approach to the patient with fever and neutropenia is discussed in detail in Chapter 260. Neutropenia with fever is a clinical emergency because patients are at risk for hemodynamic collapse and septic shock. Therefore, such patients should be evaluated thoroughly and cultured promptly, and empiric antibiotics should be administered within 30 to 60 minutes of presentation while awaiting culture results. The timely administration of antibiotics in neutropenic patients

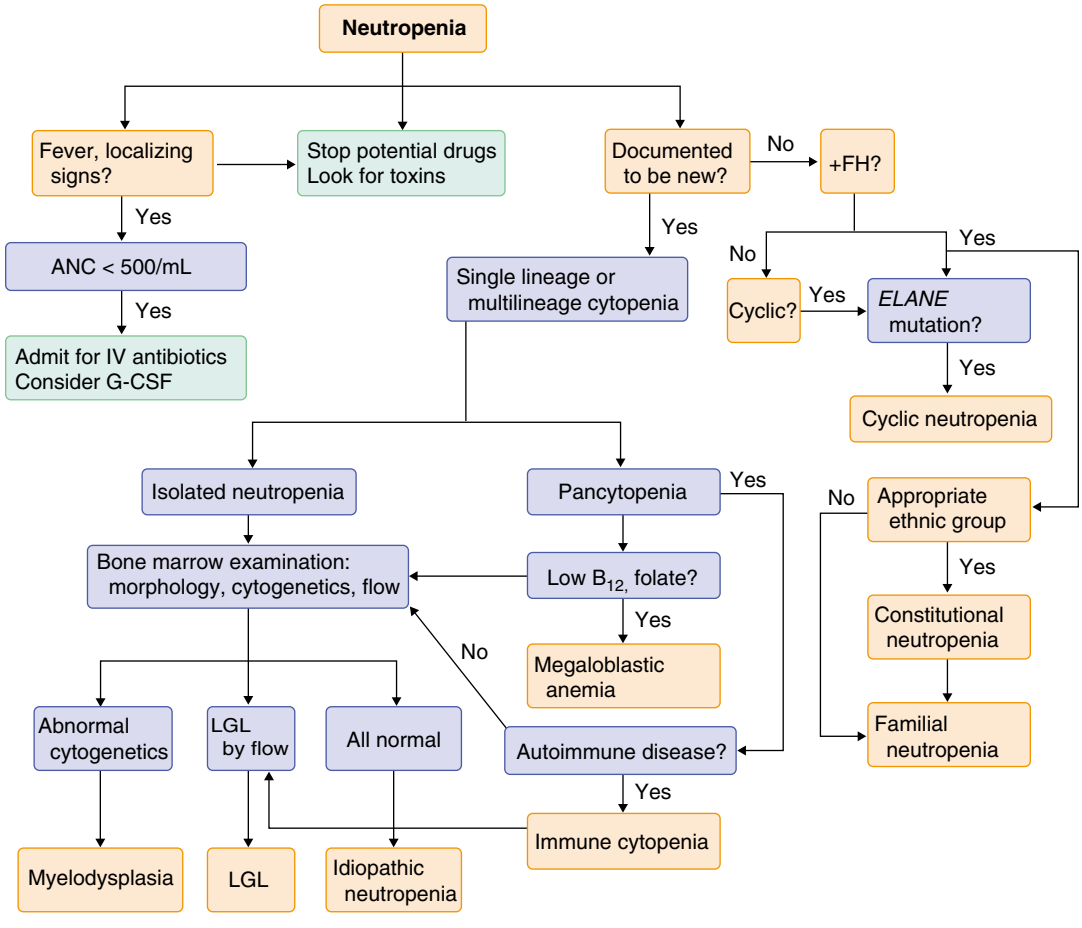

FIGURE 153-7. Diagnostic approach to neutropenia. ANC = absolute neutrophil count; *ELANE* = neutrophil elastase gene; FH = family history; G-CSF = granulocyte colony-stimulating factor; IV = intravenous; LGL = large granular lymphocyte syndrome.

at the onset of fever confers significant clinical benefit, with more rapid response and improved survival. The choice of treatment of patients with fever and neutropenia in the setting of cancer chemotherapy is based on the initial history and physical examination as well as a structured assessment of risk (Chapter 260).[15]

Other Neutropenias

Patients with immune neutropenia are typically treated with immunosuppressive therapy, including steroids, antithymocyte globulin, or cyclosporine, aimed primarily at treatment of the underlying autoimmune disease. Patients usually respond to G-CSF, although this treatment may induce a flare of joint symptoms in the setting of rheumatoid arthritis. Patients with the large granular lymphocyte syndrome often respond to low-dose methotrexate (10 mg/m^2 orally once a week), cyclosporine (100 to 600 mg or 2 to 10 mg/kg orally daily), or low-dose cyclophosphamide (50 to 100 mg orally daily).

Patients with *congenital neutropenia*, including idiopathic, severe congenital, or cyclic neutropenia, are usually successfully managed with G-CSF for years. With G-CSF, however, life expectancy has been extended into adulthood. Therapy is daily and chronic, given by subcutaneous injection, with doses varying by the type of neutropenia and the individual responsiveness to therapy. It is usually well tolerated, although accelerated bone loss has been observed. Growth and development appear unaffected. Patients with severe congenital neutropenia typically require the highest doses, whereas those with idiopathic neutropenia require the lowest.

In adults with *chronic idiopathic neutropenia*, G-CSF should be reserved for acute febrile episodes unless the patient has recurrent infections. Adults with chronic idiopathic neutropenia treated with G-CSF may experience significant side effects, including fever, gastrointestinal symptoms, and splenomegaly. Consequently, when adults with chronic idiopathic neutropenia require chronic G-CSF, it should be administered at the lowest dose necessary to prevent infections; it is usually sufficient to treat to maintain the absolute neutrophil count in the range of 300 to 500. Cyclic neutropenia is successfully treated with G-CSF and is not associated with an increased risk for leukemic transformation.

Pure white cell aplasia is immune mediated, and removal of the thymoma in thymoma-associated cases may not be sufficient for remission. Adjuvant therapy with cyclophosphamide, corticosteroids, cyclosporine, and intravenous immunoglobulin may be needed.

For patients with an inflammatory, infectious, or drug-induced neutropenia, the recommendation is to treat the underlying condition or stop the offending agent.

The use of antibiotics to prevent infection in other patients with chronic neutropenias has not been extensively studied but is typically not recommended and should be based on clinical context. There is no evidence that a low bacterial diet can prevent infection or mortality in neutropenic cancer patients.[A3]

Stem cell transplantation (Chapter 163) can be curative for a number of the congenital neutropenia and bone marrow failure syndromes, including Fanconi anemia. It is, however, not without risk and should therefore be reserved for patients with severe neutropenia complicated by recurrent infection definitively shown to be due to marrow failure.

LEUKOPENIA DUE TO DEFICIENCY OF OTHER CELL LINES

Lymphocyte production takes place in a variety of anatomic sites, and lymphocyte trafficking from those sites is bidirectional, making it difficult to understand lymphocyte dynamics in the same way that we do for neutrophils. Despite this, the peripheral lymphocyte count seems to be maintained in a narrow range at 2000 to 4000/μL, 20% of which are B cells and 70% of which are T cells. Lymphocytopenia is a total lymphocyte count of less than 1500/μL. It can reflect decreased production, defective trafficking, or increased loss or destruction. Decreased production can result from protein and calorie malnutrition; lymphocyte progenitor pool injury secondary to radiation, chemotherapy, or immunosuppressive agents; and congenital immunodeficiency states. Endogenous or exogenous glucocorticoid excess can cause lymphocytopenia by altering lymphocyte trafficking. This can also occur as the result of acute bacterial or fungal infections, certain viral infections, and granulomatous disease. Finally, many viruses cause direct destruction of lymphocytes, as do antilymphocyte antibodies seen in patients with underlying autoimmune diseases. Lymphocytes can also be lost from intestinal lymphatics in cases of protein-losing enteropathy, primary disease of the gut or intestinal lymphatics, or gut edema secondary to severe heart failure. Lymphocytopenia should prompt comprehensive assessment of the immune system, including lymphocyte subtyping, quantitative immunoglobulins, and skin testing to detect deficiencies of cell-mediated immunity. Treatment is aimed at the underlying disease, but intravenous immunoglobulin can be administered to patients with hypogammaglobulinemia, and transplantation can be performed in patients with severe deficiencies of cell-mediated immunity due to impaired lymphocyte production and function.

Monocytopenia, eosinopenia, and basophilopenia can accompany bone marrow failure syndromes or acute infection, malignancy, or severe injury and is thought to reflect elevations in glucocorticoids, prostaglandins, and epinephrine. These humoral factors have the greatest impact on eosinophils, and absence of eosinopenia in these settings should prompt suspicion for adrenal insufficiency, a primary myeloproliferative syndrome, parasitic infection, or primary hypereosinophilic syndrome. Monocytopenia is less frequent, probably owing to the diverse roles monocytes play in normal human physiology; prolonged and extreme monocytopenia may not be compatible with life.

154 APPROACH TO THE PATIENT WITH LYMPHADENOPATHY OR SPLENOMEGALY

JANE N. WINTER

LYMPHADENOPATHY

Lymphadenopathy is very common in children and adolescents but is less common in adults. Lymph nodes are secondary lymphoid tissues located along the course of the lymphatic vessels. These round or bean-shaped structures typically measure less than 1 cm in diameter and are strategically situated to filter lymphatic fluid and to intercept microorganisms and other antigens. The hilus is the point of indentation in these otherwise round tissues where blood vessels enter and leave the lymph node. Lymphatic fluid enters the lymph node in afferent lymphatic vessels that empty into the subcapsular sinus, traverses the lymph node, and then leaves through a single efferent lymphatic at the hilus. Lymph nodes consist of B and T lymphocytes, macrophages, and dendritic cells that interact to generate an immune response to the antigens transported in the lymphatic fluid. These cells function together to generate the normal immune response by means of antigen processing, presentation, and recognition and the resulting proliferation of effector B and T lymphocytes.[1]

Lymph node enlargement generally results from cellular proliferation and expansion of lymph node components associated with the normal immune response to foreign antigens. Alternatively, it can be caused by infiltration of the lymph node by a neoplastic process or deposition of a foreign substance (e.g., in storage disease).

CLINICAL MANIFESTATIONS

Lymphadenopathy is usually noted incidentally by the patient on self-examination or is noted by a family member. Sometimes it is first detected by a physician on a physical examination. However, an increasing number of patients with lymphadenopathy are identified incidentally when they undergo imaging for unrelated issues (e.g., chest radiography for infectious symptoms; magnetic resonance imaging [MRI] of the spine for back pain related to a disc herniation). Occasionally an enlarged lymph node can become tender or become large enough to cause direct symptoms.

154 APPROACH TO THE PATIENT WITH LYMPHADENOPATHY OR SPLENOMEGALY

JANE N. WINTER

LYMPHADENOPATHY

Lymphadenopathy is very common in children and adolescents but is less common in adults. Lymph nodes are secondary lymphoid tissues located along the course of the lymphatic vessels. These round or bean-shaped structures typically measure less than 1 cm in diameter and are strategically situated to filter lymphatic fluid and to intercept microorganisms and other antigens. The hilus is the point of indentation in these otherwise round tissues where blood vessels enter and leave the lymph node. Lymphatic fluid enters the lymph node in afferent lymphatic vessels that empty into the subcapsular sinus, traverses the lymph node, and then leaves through a single efferent lymphatic at the hilus. Lymph nodes consist of B and T lymphocytes, macrophages, and dendritic cells that interact to generate an immune response to the antigens transported in the lymphatic fluid. These cells function together to generate the normal immune response by means of antigen processing, presentation, and recognition and the resulting proliferation of effector B and T lymphocytes.[1]

Lymph node enlargement generally results from cellular proliferation and expansion of lymph node components associated with the normal immune response to foreign antigens. Alternatively, it can be caused by infiltration of the lymph node by a neoplastic process or deposition of a foreign substance (e.g., in storage disease).

CLINICAL MANIFESTATIONS

Lymphadenopathy is usually noted incidentally by the patient on self-examination or is noted by a family member. Sometimes it is first detected by a physician on a physical examination. However, an increasing number of patients with lymphadenopathy are identified incidentally when they undergo imaging for unrelated issues (e.g., chest radiography for infectious symptoms; magnetic resonance imaging [MRI] of the spine for back pain related to a disc herniation). Occasionally an enlarged lymph node can become tender or become large enough to cause direct symptoms.

ABSTRACT

Lymphadenopathy is usually first noted by the patient on self-examination, but both lymphadenopathy and especially splenomegaly are often first detected incidentally when imaging is performed for an unrelated issue. The differential diagnosis of lymphadenopathy and splenomegaly is broad, with infections, autoimmune disorders, and malignancies representing the vast majority of cases. A careful and complete history is the first and most important step in the assessment of the patient with lymphadenopathy and/or splenomegaly, including travel history and possible exposures to infectious agents as well as sexual and family history. Similarly, the physical examination must be complete, with attention to the distribution of the adenopathy, as well as to the size and associated erythema or tenderness of the enlarged nodes. In the patient with splenomegaly, its overall size, the presence of associated lymphadenopathy, tonsillar enlargement, and hepatomegaly are of particular importance. A complete blood count with review of the peripheral smear may be especially helpful in identifying the underlying cause. Biopsy is indicated when malignant lymphadenopathy is suspected. For splenomegaly, however, close observation rather than biopsy or splenectomy is often the best course of action in the asymptomatic patient.

KEYWORDS

lymphadenopathy
lymphoproliferative disorder
splenomegaly
hypersplenism
splenectomy

TABLE 154-1 TAKING A COMPLETE HISTORY IN THE ADULT PATIENT WITH LYMPHADENOPATHY

History of present illness
Duration, recent changes
Associated symptoms: fevers, drenching night sweats, shaking chills, weight loss, sore throat, arthritis or arthralgias, rash or skin lesions, pruritus, shortness of breath, chest pain
Ill contacts, recent and remote travel, tick or insect bites
Past medical history
Autoimmune disease, history of immunosuppressive therapy, history of infectious disease, history of recent vaccination
Family history
Malignancy, especially hematologic malignancy, or infection
Autoimmune disease
Social history
Sexual activity—risk for HIV infection, other sexually transmitted diseases
Occupation—exposure to toxins, livestock, pets
Smoking or drinking
Medications: immunosuppressive agents, phenytoin, allopurinol, antibiotics

HIV = human immunodeficiency virus.

TABLE 154-2 CLUES TO THE CAUSE OF LYMPHADENOPATHY

Age
Symptoms
Localized versus generalized lymphadenopathy
Specific location/distribution
Tenderness, warmth, overlying erythema, mobility, pulsatile
Size

DIAGNOSIS

Lymph nodes that are larger than 1 cm are generally considered to be abnormal, although adenopathy in some locations is considered abnormal and worthy of investigation even when subcentimeter in size (supraclavicular, epitrochlear, or popliteal lymph nodes).

History and Physical Examination

A careful and complete history is the first and most important step in the evaluation of the patient with lymphadenopathy (Table 154-1). The age of the patient, recent travel history, possible infectious or toxic exposures through employment or hobbies, recent immunizations (e.g., COVID-19 vaccination is a frequent cause of unilateral axillary adenopathy),[2] current medications, and social, sexual, and family history may provide important clues to the cause (Table 154-2). A complete review of systems is required. Not only can the presence of symptoms be informative, but also their pattern, character, and duration (e.g., the high spiking fevers characteristic of Hodgkin lymphoma, known as Pel-Ebstein fevers) may suggest a cause. Similarly, particular symptoms such as pruritus suggest specific diagnoses (e.g., also Hodgkin lymphoma).

The physical examination must also be meticulous with attention not only to the distribution of the adenopathy but also to the presence of other physical findings (e.g., tonsillar enlargement in the patient with cervical adenopathy and Burkitt lymphoma [Chapter 171], parotid enlargement in Sjögren syndrome [Chapter 247], rash in T-cell lymphomas [Chapter 171], joint findings in autoimmune disorders, or a breast mass in the patient with axillary lymphadenopathy) (Table 154-3). Malignant lymph nodes are generally painless, whereas nodes that represent infection may be tender. Although exceptions occur, lymphadenopathy resulting from metastatic solid tumor is characteristically hard and may be fixed or matted, whereas lymphadenopathy representing hematologic malignancies is typically soft and may be mobile. Although borderline and slightly enlarged lymph nodes are commonly related to infectious causes, sizeable nodes are worrisome for malignancy and warrant prompt investigation. Often, no cause is identified, and careful follow-up is required.

Differential Diagnosis

The differential diagnosis of lymphadenopathy is vast. Whether lymphadenopathy is localized or generalized, its location, and the age of the patient all help to focus the investigation into its cause. Diffuse lymphadenopathy may occur in the setting of generalized infections, systemic disorders of the immune system, or widespread neoplasia (Table 154-4).

TABLE 154-3 EVALUATING THE PATIENT WITH LYMPHADENOPATHY

Complete physical examination with particular attention to:
Tonsillar enlargement, evidence of superior vena cava syndrome
Attention to all lymph node groups including epitrochlear, femoral
Hepatosplenomegaly
Rash
Joints, deformities
Preliminary laboratory examination
Complete blood count with differential, platelet count
Sedimentation rate, testing for mononucleosis in the right setting
Imaging
Chest radiograph (assess for mediastinal mass, hilar enlargement, infiltrate)
Ultrasound for children up to age 14 years
CT with intravenous contrast or contrast-enhanced MRI
PET/CT not recommended unless diagnosis of lymphoma or other malignancy
Pathologic diagnosis
Needle aspiration for investigation of infectious causes
Core biopsy if excisional biopsy unsafe
Excisional biopsy preferred especially if malignancy suspected

CT = computed tomography; MRI = magnetic resonance imaging; PET = positron emission tomography.

TABLE 154-4 DIFFERENTIAL DIAGNOSIS OF LYMPHADENOPATHY

CAUSES	EXAMPLES
Infectious	
Bacteria	Group A streptococcus, staphylococcal skin infections, syphilis, cat-scratch disease, *Chlamydia trachomatis*, typhoid fever, tuberculosis
Fungi	Histoplasmosis, blastomycosis, coccidioidomycosis
Parasites	Malaria, toxoplasmosis
Viruses	Infectious mononucleosis (Epstein-Barr virus), cytomegalovirus, HIV
Immune mediated	
Autoimmune disorders	Rheumatoid arthritis, systemic lupus erythematosus
Drug reactions	
Malignant	
Hematologic	Lymphoma, leukemia, myeloproliferative neoplasms
Solid tumors	Metastatic to lymph nodes
Unusual	
Storage disease	Gaucher disease, Niemann-Pick disease
Sarcoidosis	
Castleman disease	
Kawasaki vasculitis	
Kikuchi lymphadenitis	
Kimura disease	
Endocrinopathies	Addison disease
Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease)	

HIV = human immunodeficiency virus.

Localized lymphadenopathy usually but not always results from a regional problem, such as infection or malignancy. The particular site may be informative. For example, recurrent sore throats and upper respiratory infections are regularly associated with tender submandibular and/or cervical adenopathy.[3] However, although cervical adenopathy in adults can be reactive hyperplasia from systemic infection, it is commonly caused by malignancies such as head and neck carcinomas, adenocarcinomas, small cell lung cancer, and lymphoma.[4] Epitrochlear or supraclavicular adenopathy is problematic in any adult or child, and it signifies likely disease. Inguinal adenopathy is common, often related to infection or trauma to the lower extremities, and often of little concern in the absence of other findings. Thoracic and mediastinal adenopathy may be caused by lung cancer (Chapter 177) but also by a variety of nonmalignant

conditions including sarcoidosis (Chapter 83) and Castleman disease (Chapter 359) in addition to infection.[5]

Worldwide, infection by bacteria, mycobacteria, fungi, chlamydia, parasites, and viruses are the major causes of lymph node enlargement. Lymph node enlargement in the drainage region of any pyogenic infection is expected. Dramatic regional lymph node enlargement with fluctuant lymph nodes (i.e., buboes) is a hallmark of infection with the coccobacillus *Yersinia pestis* (Chapter 288), which causes bubonic plague. In cat-scratch fever, enlarged nodes close to the site of the flea bite carrying *Bartonella henselae* are common presenting signs (Chapter 291). Mediastinal lymphadenopathy may occur in inhalational anthrax (Chapter 272). Cervical adenopathy is commonly a manifestation of tuberculosis (Chapter 299). In contrast, diffuse adenopathy may represent a systemic infection with Epstein-Barr virus (i.e., infectious mononucleosis; Chapter 348), cytomegalovirus (Chapter 347), or human immunodeficiency virus (HIV; Chapter 359), or with the parasite *Toxoplasma gondii* (Chapter 320).

Autoimmune disorders may be associated with either localized or generalized lymphadenopathy. Lymph node enlargement in this setting is especially challenging given the increased frequency of malignant lymphoproliferative disorders in these patients. Biopsy (excisional when possible) and expert hematopathology consultation are required to exclude the possibility of lymphoma. Lymphadenopathy occurring as a result of a drug reaction is uncommon,[6] but it may be exceptionally difficult to distinguish histopathologically from malignant lymphoma. A wide range of drugs, including antiepileptics and antibiotics, have been reported to cause lymphadenopathy, but associated rash, eosinophilia, and liver function abnormalities are helpful in distinguishing a drug reaction (Chapter 234) from other causes.

Malignancy commonly manifests as lymphadenopathy. Enlarged lymph nodes (Fig. 154-1) may be involved or replaced by a hematologic malignancy such as Hodgkin (Chapter 172) or non-Hodgkin lymphoma (Chapter 171), or they may represent a site of metastasis from a solid tumor, most often occurring in the drainage area of the primary tumor.[7] For example, breast cancer (Chapter 183) is often accompanied by ipsilateral axillary nodal involvement and prostate cancer by iliac node involvement. Distant spread to the lymph nodes may also occur.

In addition to infectious, autoimmune, and malignant causes of lymphadenopathy, less common causes include storage diseases (as in Gaucher or Niemann-Pick disease; Chapter 192) or amyloidosis (Chapter 174; associated with a hematologic malignancy such as multiple myeloma or non-Hodgkin lymphoma, an inherited form of the disease, or with chronic inflammation). Sarcoidosis (Chapter 83) may manifest as enlarged lymph nodes, as can endocrinopathies such as thyroid disease (Chapter 207) or adrenal insufficiency (Chapter 208). Benign entities such as congenital lymphovascular malformations and branchial cleft cysts may present as a neck mass in a child.

Blood Testing

A routine complete blood count should be obtained. When signs and symptoms are consistent with an infectious cause, atypical lymphocytosis suggests Epstein-Barr virus infection, which can be confirmed by serology (Chapter 348).

Imaging

Imaging with computed tomography (CT) or MRI, with the latter preferred when radiation exposure is to be avoided such as during pregnancy, is the first step in the evaluation of worrisome palpable adenopathy in adults.[8] Ultrasonography is recommended as the preferred approach for children with cervical adenopathy and is also useful in adults for determining the size of the node and the possible presence of multiple nodes.[9,10] Clearly, borderline adenopathy or lymphadenopathy associated with symptoms or history suggestive of a benign origin (e.g., mononucleosis in a college student) does not merit immediate imaging and may be watched. Combined positron emission tomography (PET) and CT (PET/CT) should not be an initial test[11] but is very useful for staging and evaluation during and after treatment of patients who are diagnosed with a malignant lymphoma or a variety of solid tumors (Fig. 154-2).

Studies for infectious agents including cultures and special stains for infectious agents, immunophenotypic analysis by flow cytometry, and molecular studies complement morphology in making a diagnosis. In contrast, if head and neck cancer is in the differential diagnosis, the patient should have a complete ear, nose, and throat examination at the outset to avoid complicating subsequent surgery.

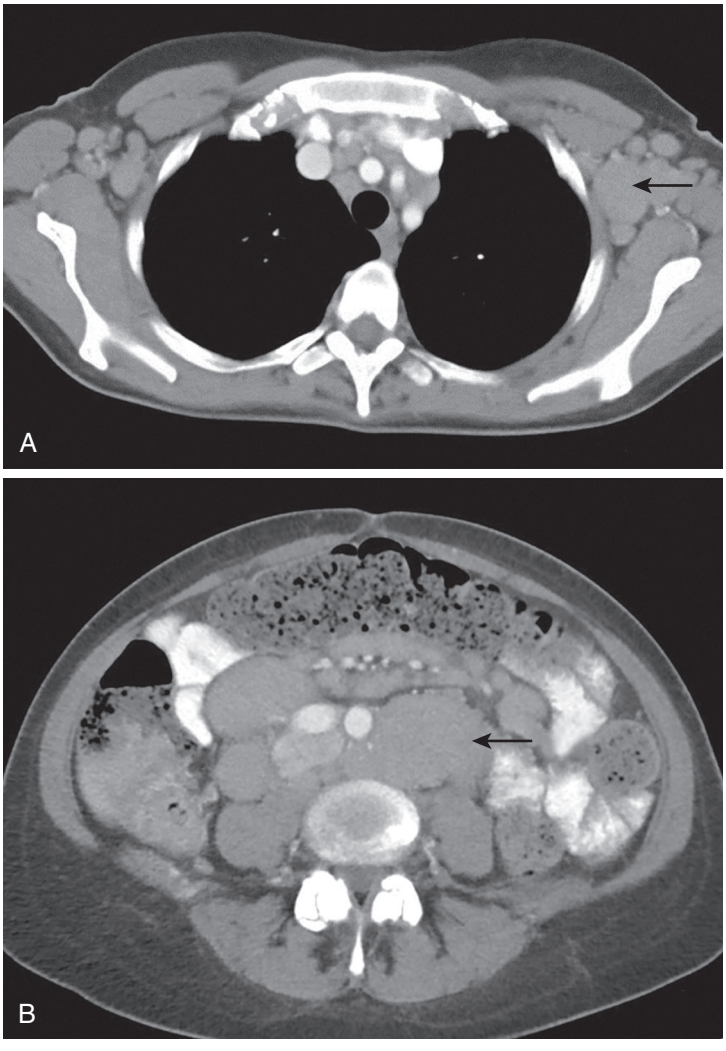

FIGURE 154-1. Axillary (A) and retroperitoneal lymph nodes (B) in a patient with follicular lymphoma. *Arrows* indicate examples of enlarged lymph nodes.

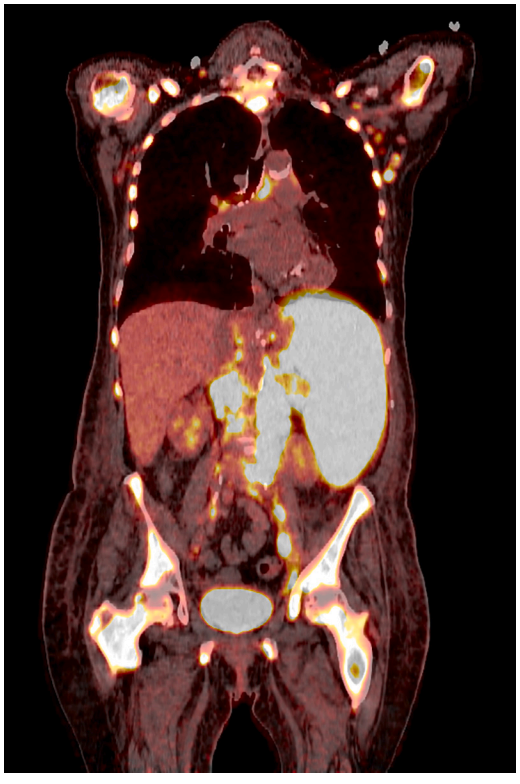

FIGURE 154-2. Fluorodeoxyglucose (FDG)-positron emission tomography (PET)/computed tomographic (CT) scan. The FDG-PET/CT scan demonstrates involvement of the spleen, lymph nodes, and bone in a patient with lymphoma.

Evaluation of a patient with incidentally noted lymphadenopathy on an imaging study poses a special challenge. For example, evaluation of the patient with incidentally noted intra-abdominal or pelvic adenopathy, like that of the patient with a new palpable mass, requires that the clinician integrate the clinical history and radiographic findings. A comparison of the radiologic findings to prior imaging studies can often eliminate concern if the findings are discovered to be long standing. Imaging findings considered worrisome by the American College of Radiology include (1) short axis diameter 1 cm or larger in the retroperitoneum; (2) abnormal architecture (round, indistinct hilum); (3) presence of enhancement (necrosis; hypervascularity); and (4) increased number of nodes defined as a cluster of three or more in a single nodal station or two or more in at least two regions. Biopsy should be considered if the nodes fall into any of these categories and there is clinical or laboratory evidence supporting the presence of a lymphoproliferative disorder. In many cases, the patient may be followed with repeat imaging in 3 to 6 months. If stable for 1 year, an abnormal lymph node or group of lymph nodes is most likely benign.

The location of the enlarged node(s), size, consistency, presence of generalized lymphadenopathy or hepatosplenomegaly, or associated symptoms are all helpful in developing an individualized approach. If nodes are large, 2 to 3 cm in size, and firm with associated symptoms, the risk for malignancy is high, and a diagnostic procedure should be performed expeditiously. A complete blood count with differential and examination of the peripheral smear along with a plain chest radiography may be helpful in sorting out which patient is best served by observation for what may be infectious mononucleosis or another infectious and uncomplicated process and who should proceed quickly to biopsy. A short course of antibiotics with close observation is often the preferred strategy with little risk if the patient is reliable and will return if the lump grows rather than regresses. Steroids should be avoided because they may mask the symptoms and cause shrinkage of the nodes in hematologic malignancies.

Biopsy

The decision to perform a biopsy of a lymph node depends on the clinical history and presentation as well as the ease with which a biopsy can be performed. For patients with symptoms, an early biopsy of a palpable lymph node may provide an answer to a puzzling case[12] but may add to the confusion if the biopsy result is not definitive. An excisional rather than a core biopsy is most likely to provide a definitive diagnosis,[13] but it is not practical in all cases. When no easily accessible peripheral nodes are available for biopsy, a core biopsy may be obtained by the interventional radiologists with the assistance of ultrasound or CT guidance. Fine-needle aspiration may be adequate to diagnose a solid tumor or infection but is insufficient for distinguishing malignant lymphoma from a reactive lymph node, and it is discouraged if lymphoma is in the differential diagnosis. An excisional biopsy remains the gold standard. Face-to-face discussion between the clinician and the pathologist is the most effective approach to determining a diagnosis, especially for the most challenging cases.

TREATMENT AND PROGNOSIS

The treatment of lymphadenopathy focuses on treatment of the underlying disease, which also determines prognosis. In some tumors, such as breast cancer (Chapter 183) and ovarian cancer (Chapter 184), removal of local lymph nodes is an important part of therapy.

SPLENOMEGALY

Splenomegaly is present in about 2% of adults in the United States, with no predilection by gender, age, or ethnicity. Causes include a wide variety of infections, primary liver disease, benign hematologic diseases, and malignancies.

The spleen is the largest lymphatic organ in the body, and some liken it to a very large lymph node. Similar to lymph nodes, the spleen has multiple and diverse functions, including its role as a filter removing defective red blood cells and infectious agents, its important role in immune response to blood-borne antigens, and a role in regulating blood volume.

Consistent with its multiple functions and its role as a massive filter, the spleen has an open circulation with three compartments: the white pulp, marginal zone, and red pulp. Blood enters the spleen through the splenic artery and its branches, filters through the splenic cords and periarterial lymphatic sheath, and is exposed in the white pulp to immunologically active cells including macrophages, B lymphocytes, and T lymphocytes. In the white pulp, microorganisms and foreign proteins are recognized, and an immune response to blood-borne antigens is initiated. In splenectomized individuals, the absence of this splenic function predisposes to certain infections, especially infections with encapsulated organisms such as *Streptococcus pneumoniae*.

Separating white pulp from red, the marginal zone acts as a transition zone. More than half the volume of the spleen is composed of splenic red pulp and consists primarily of erythrocytes along with macrophages, dendritic cells, and other white blood cells. Senescent or defective red blood cells are identified and destroyed in the red pulp. The process of hemolysis may be mechanical and/or immunologic as in autoimmune hemolytic anemia, in which the antibody-coated red blood cells are phagocytosed by macrophages. Perhaps less well appreciated, the spleen plays a role in regulating blood volume by means of a variety of mechanisms, including release of blood through splenic contraction and the splenorenal reflex that promotes retention of fluid and sodium by the kidneys during septic shock.

CLINICAL MANIFESTATIONS

Splenomegaly is commonly detected as an incidental finding on imaging performed for what appears to be an unrelated issue such as diverticulitis or nephrolithiasis. Given the obesity epidemic and the increasing reliance on testing rather than careful physical examination, it is uncommon for splenomegaly to be detected first on physical examination except as part of a careful evaluation of a patient who has a known predisposing condition.

Except with massive splenomegaly or acute obliteration of the splenic artery or vein, the patient is unlikely to have specific complaints related to splenomegaly itself. Pain in the left upper quadrant sometimes radiating to the left shoulder may be the first indication of a splenic infarct or an enlarged spleen. Rarely, the catastrophic signs and symptoms of splenic rupture are the first indications of splenomegaly. Unexplained weight loss related to early satiety caused by compression of the stomach by the enlarged spleen or unexplained cytopenias caused by hypersplenism may be the first indication of splenomegaly.

DIAGNOSIS

In contrast to lymphadenopathy, an enlarged spleen discovered on physical examination is nearly always abnormal and requires explanation. As with lymphadenopathy, the differential diagnosis of splenomegaly is wide ranging (Table 154-5), and the same principles hold. First, a careful history and physical examination, with attention to the age of the patient, the size of the spleen, and associated symptoms, will often but not always guide the investigation to the underlying cause. The majority of cases are due to infection, autoimmune disorders, or malignancies, but oftentimes no cause is identified, so careful follow-up is required.

TABLE 154-5 DIFFERENTIAL DIAGNOSIS OF SPLENOMEGALY

CAUSES	EXAMPLES
Infectious	
Bacteria	Endocarditis, brucellosis, syphilis, tuberculosis, Rocky Mountain spotted fever
Fungi	Histoplasmosis, toxoplasmosis
Parasites	Malaria, leishmaniasis
Viruses	Infectious mononucleosis (Epstein-Barr virus), HIV, cytomegalovirus
Immune mediated	
Autoimmune disorders	Rheumatoid arthritis, systemic lupus erythematosus, autoimmune hemolytic anemia
Drug reaction	Phenytoin
Malignant	
Hematologic	Lymphoma, leukemia, myeloproliferative neoplasm
Solid tumor	Metastatic to spleen
Congestive	Liver disease, portal vein thrombosis, congestive heart failure
Nonmalignant hematologic disorders	Hereditary spherocytosis, congenital or acquired hemolytic anemias, hemoglobinopathies, extramedullary hematopoiesis
Unusual	
Storage disease	Gaucher disease, Niemann-Pick disease
Sarcoidosis	
Cysts, pseudocysts	
Amyloidosis	

HIV = human immunodeficiency virus.

History

Similar to the approach to lymphadenopathy, a careful and complete history is the first and most important step in the evaluation of the patient with splenomegaly. The age of the patient, travel history, possible infectious or toxic exposures through employment or hobbies, recent immunizations, current medications, and social, sexual, and family history all may contribute important clues to the cause. A complete review of systems is required. A review of old records including imaging may provide evidence that splenomegaly is long-standing.

Physical Examination

Despite many approaches to palpating the spleen, a borderline or slightly enlarged spleen may be difficult to appreciate on examination. Positioning the patient in the right lateral decubitus position with knees slight flexed is a useful approach, especially for right-handed examiners. The examination should begin very low in the pelvis and work upwards to the left upper quadrant so as not to miss the edge of a massively enlarged spleen. Inspection and percussion combined with palpation provide the best chance of identifying the enlarged spleen. The patient should take deep breaths while checking for the tip of the spleen as it descends with deep inspiration. Splenomegaly is typically recorded as the number of centimeters the spleen descends below the left costal margin in the midclavicular line on deep inspiration. The physical examination in the patient with splenomegaly should be meticulous, including attention to the presence of lymphadenopathy, jaundice, tonsillar enlargement, joint effusions or swelling, and hepatomegaly.

Differential Diagnosis

The infectious causes of splenomegaly are myriad.[14,15] Geography and travel history are often important clues to an underlying infection. The most likely causes of splenomegaly in equatorial Africa or in a recent African immigrant are different from the causes in a North American urbanite. Bacterial infections commonly associated with splenomegaly include endocarditis (Chapter 61), brucellosis (Chapter 286), typhoid fever (Chapter 284), and rickettsial disorders such as Rocky Mountain spotted fever (Chapter 302). Mycobacterial infections including typical (Chapter 299) and atypical (Chapter 300) mycobacteria may manifest with splenomegaly, as can fungal infections such as histoplasmosis (Chapter 308). Among the parasitic disorders, malaria (Chapter 316) is nearly always accompanied by an enlarged spleen and should be high on the differential diagnosis list in the proper setting. Epstein-Barr virus (Chapter 348), which is the cause of infectious mononucleosis, is a common cause of splenomegaly that is usually self-limited. HIV (Chapter 359) may also be associated with splenomegaly, although often the causative agent is a coexisting infection with hepatitis C virus.

Autoimmune disorders such as rheumatoid arthritis (Chapter 243) and systemic lupus erythematosus (Chapter 245) are commonly associated with mild to moderate splenomegaly. Felty syndrome is characterized by splenomegaly, usually in the setting of long-standing rheumatoid arthritis, with associated neutropenia. Autoimmune hemolytic anemia (Chapter 146) is characterized by splenomegaly. Reactions to a variety of commonly prescribed drugs such as antibiotics may result in splenomegaly because of direct effects on the spleen, serum sickness (Chapter 36), or indirectly through effects on the liver.

Hematologic malignancies including myeloproliferative neoplasms frequently manifest with splenomegaly. Patients with lymphoproliferative disorders such as chronic lymphocytic leukemia (Chapter 169) or mantle cell lymphoma (Chapter 171) will in many cases have easily appreciated lymphadenopathy in addition to a palpable spleen. Isolated splenomegaly without associated lymphadenopathy is characteristic of hairy cell leukemia and myeloproliferative neoplasms such as primary myelofibrosis (Chapter 152).[16] Splenomegaly with weight loss related to compression of the stomach and early satiety may be the presenting complaint. Solid tumors may sometimes metastasize to the spleen and result in its enlargement, but this occurrence is unusual. Among solid tumors, malignant melanoma (Chapter 188) is the one most likely to be associated with splenic involvement, but even so, palpable splenomegaly is rare.

Congestive splenomegaly may occur as the result of chronic liver disease with portal hypertension (Chapter 139) or in the setting of splenic or portal vein thrombosis (Chapter 129). Disorders that result in excessive destruction of abnormal red blood cells such as hereditary spherocytosis (Chapter 147) or hemoglobinopathies are also associated with splenomegaly. Storage diseases such as Gaucher disease (Chapter 192), sarcoidosis (Chapter 83), amyloidosis (Chapter 174), thyrotoxicosis (Chapter 207), and hemophagocytic lymphohistiocytosis (Chapter 155) are among the other less common causes of splenomegaly.

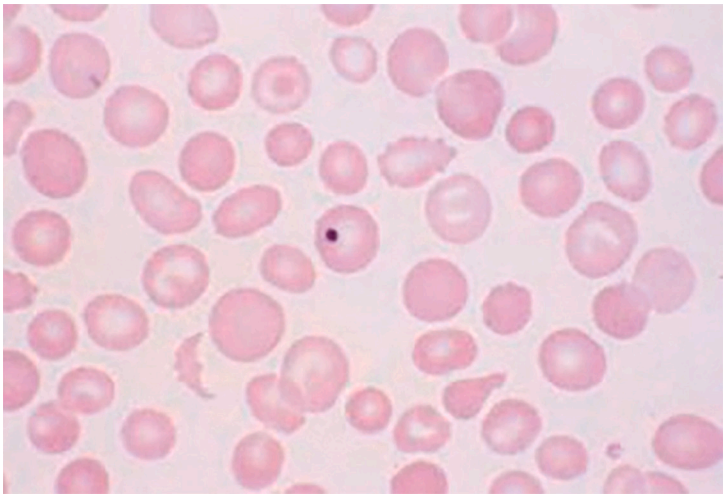

FIGURE 154-3. Howell-Jolly body in an erythrocyte. This finding is evidence of prior splenectomy or a nonfunctional spleen.

Laboratory Evaluation

Although the otherwise asymptomatic patient may be monitored, the symptomatic patient requires a diagnosis so that appropriate treatment may be initiated. Laboratory studies, especially the complete blood count and peripheral blood smear, are important tools in the investigation of the patient with splenomegaly. An enlarged spleen is frequently hyperfunctional ("hypersplenism") and sequesters red cells and platelets, thereby leading to anemia and thrombocytopenia. Leukopenia may also occur. In the presence of hypersplenism, examination of the peripheral smear (Chapter 143) in the patient with splenomegaly may show nucleated red blood cells and red cell abnormalities characteristic of chronic liver disease. The presence of abnormal lymphocytes (e.g., cells with projections as in hairy cell leukemia or with villous projections in splenic marginal zone lymphoma with villous lymphocytes) suggests the presence of a malignant leukemia or lymphoma. The presence of lymphoblasts points to acute lymphoblastic leukemia. In the absence of a functioning spleen, basophilic inclusions representing nuclear remnants, known as *Howell-Jolly bodies*, are seen in circulating red blood cells. The presence of Howell-Jolly bodies (Fig. 154-3) in peripheral blood indicates that the patient has either undergone splenectomy or has a nonfunctioning spleen, as in patients with sickle cell disease who have experienced repeated splenic infarcts.

Flow cytometric analysis can identify the abnormal cell population in many cases. A bone marrow aspirate and biopsy with immunohistochemistry, special stains, flow cytometric analysis, fluorescent in situ hybridization, cytogenetics, and additional molecular testing for particular mutations may be required for the complete evaluation of the patient with splenomegaly and a hematologic malignancy.

Elevated lactate dehydrogenase and uric acid levels are seen in lymphoid malignancies such as Burkitt lymphoma or other aggressive non-Hodgkin lymphomas, but also in myeloid malignancies. Examination of thick smears in patients suspected of malaria may show the offending parasite. Genetic testing may confirm a suspected diagnosis (e.g., in hemophagocytic lymphohistiocytosis).

Imaging

Not all palpable spleens are abnormal, especially in very thin individuals. The least invasive and most inexpensive approach to imaging the spleen is ultrasound, an approach that allows for sequential and accurate measurements. By ultrasound criteria, a spleen that is 13 cm or greater in length and more than 5 cm in thickness qualifies as enlarged.

In comparison with ultrasound, CT scans generally focus on the entire abdomen, not just the spleen, and provide important information that often provides an explanation for the splenomegaly. CT scans also will show

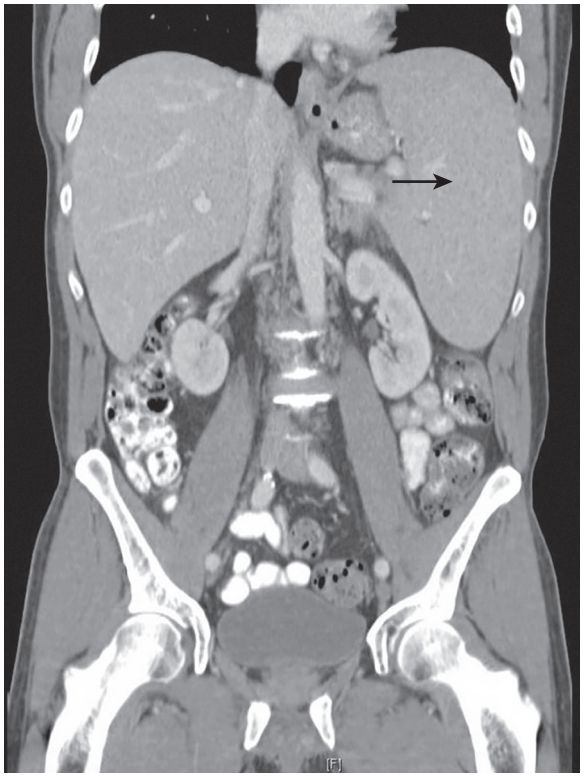

FIGURE 154-4. Splenomegaly (indicated by *arrow*) in a patient with hemophagocytic lymphohistiocytosis.

whether the spleen is diffusely enlarged or enlarged because of multiple nodules (Fig. 154-4). Fluorodeoxyglucose-PET does not distinguish among a variety of malignancies, infections, and other causes of splenomegaly, and it generally is not useful in the diagnostic evaluation of the patient with splenomegaly.

Biopsy

Because of the spleen's location and propensity to bleed, needle aspiration or core biopsy of the spleen is performed only at centers skilled and experienced in the procedure. If an extensive evaluation has not provided a likely explanation for splenomegaly and observation is judged to be imprudent, splenectomy may be performed laparoscopically or by laparotomy.[17,18] Because of the risk of surgical complications and long-term susceptibility to infection in splenectomized individuals, the relative risks and benefits of the procedure must be given serious consideration.[19] Once splenectomy is a possibility, immunization should proceed promptly in an attempt to reduce long-term risks. Appropriate vaccination before splenectomy and in asplenic individuals is of utmost importance (Table 154-6). Partial splenectomy is performed in some children with hereditary spherocytosis, splenic tumors, or splenic trauma in an attempt to reduce the long-term risk of sepsis.[20]

TABLE 154-6 RECOMMENDATIONS FOR PNEUMOCOCCAL, MENINGOCOCCAL, AND *HAEMOPHILUS INFLUENZAE* VACCINATION FOR ASPLENIC INDIVIDUALS

The following vaccines are used:	
Meningococcus	Quadrivalent meningococcal conjugate vaccine (Menveo) Meningococcal serogroup B vaccine (Trumenba or Bexsero)
Pneumococcus	23-valent pneumococcal vaccine (PPSV23, Pneumovax) 15-valent conjugate vaccine (PCV 15; Vaxneuvance); 20-valent conjugate vaccine (PCV 20; Prevnar 20)
Haemophilus influenzae	*H. influenza* type b (Hib) conjugate vaccine
GENERAL GUIDELINES	
• Adults with functional asplenia (e.g., those with sickle cell disease) or those who require surgical splenectomy should be immunized with pneumococcal, meningococcal, and *H. influenza* vaccines • If undergoing elective splenectomy, meningococcal, pneumococcal, and *H. influenzae* vaccines should be given at least 14 days before surgery. If not possible, they should be given after no less than 14 days after splenectomy • Some recommend that the same vaccine combination be given again 8 weeks after the initial doses • Multiple vaccines can be given at the same visit but injected at separate sites • There is some variation in the specific recommendations listed below between guidelines from the U.S. Centers for Disease Control (CDC), the U.S. Advisory Committee on Immunization Practices, various institutions, and some European agencies	
MENINGOCOCCAL VACCINES	
• Quadrivalent meningococcal conjugate vaccines: two doses of Menveo or MenQuadfi, given 2 months apart *plus* • Serogroup B meningococcal vaccines: either Trumenba (three doses at 0, 1-2, and 6 months apart) *or* Bexsero (two doses at least 1 month apart) • Boost every 5 years with Menveo, Menactra, or MenQuadfi • The two serogroup B vaccines are not interchangeable; the same vaccine product must be used for all doses in a series	
PNEUMOCOCCAL VACCINES	
• For before splenectomy: Prevnar 20 alone or Vaxneuvance followed by Pneumovax at least 8 weeks apart • For functional asplenia: Prevnar 20 alone or Vaxneuvance followed by Pneumovax at least 8 weeks apart	
***HAEMOPHILUS INFLUENZAE* VACCINE**	
• Most adults are not at risk because they have already acquired specific antibodies against it through routine childhood vaccination or previous infection. However • One dose of Hib vaccine can be given before splenectomy • One dose of Hib vaccine can be given to functionally asplenic individuals	

TREATMENT

If a likely cause, such as infectious mononucleosis or another infectious process, is identified and confirmed by testing, appropriate management should follow. The associated splenomegaly should resolve over time. Splenectomy may be indicated as part of the treatment of refractory immune thrombocytopenic purpura (Chapter 158) or inherited anemias such as hereditary spherocytosis (Chapter 147) or in cases of splenic abscess. Splenectomy also occasionally may be required for severe hypersplenism with cytopenias.

PROGNOSIS

Most incidentally identified splenic masses in asymptomatic patients will prove to be benign. When borderline in size, the significance of the incidentally noted spleen, like marginally enlarged lymph nodes, is unclear and requires follow-up. Follow-up imaging in short intervals (3 to 6 months) may establish a lesion to be unchanged and provide reassurance of its benign nature. Additional imaging modalities (e.g., MRI, PET/CT, and ultrasound) may be helpful in selecting appropriate patients for further investigation, including biopsy.

The patient without an obvious explanation for splenomegaly presents a difficult diagnostic challenge. Occult liver disease or an undiagnosed autoimmune process may emerge over time as an explanation for persistent splenomegaly in some of these patients.

Splenectomy or biopsy of focal splenic lesions may be the only diagnostic option in patients with persistent symptoms or progressive cytopenias. Splenectomy may have unintended consequences in patients with occult liver disease and portal hypertension and should be avoided in that setting. In the asymptomatic patient, close observation is often preferable to splenectomy.

155 HISTIOCYTOSES

BARRETT J. ROLLINS AND NANCY BERLINER

The histiocytoses comprise a family of diseases characterized by an accumulation of abnormal cells with features reminiscent of macrophages or dendritic cells. The term *histiocyte* refers to tissue macrophages that are the cell of origin for some histiocytoses. However, many of the other histiocytoses derive from nonmacrophage lineages or from hematopoietic stem cells.

The diagnostic category of histiocytosis embraces a number of heterogeneous but distinct clinical entities, some of which may co-occur in a single patient. Recent advances in molecular genetics provide the basis for a revised nosology that places histiocytic diseases into five groups (Table 155-1)[1,2]:

- L group. These include Langerhans cell histiocytoses and Erdheim-Chester disease because the occasional appearance of both diseases in the same patient suggests a common origin and because both diseases are characterized by somatic mutations in genes of the mitogen-activated protein kinase (MAPK) pathway. Indeterminate cell histiocytosis is also placed in the L group because it shares some characteristics with Langerhans cell histiocytosis.
- C group. These are non-Langerhans cell histiocytoses that involve the skin and/or mucosal surfaces. As in the L group, patients may present with mixtures of C group histiocytoses. They are subdivided into the xanthogranuloma and nonxanthogranuloma diseases. Some C group diseases also have a major systemic component, and mutations in MAPK pathway genes may be seen.
- M group. These are the malignant histiocytoses, which include primary malignancies such as malignant histiocytosis and secondary malignant histiocytoses that occur in the setting of leukemias, lymphomas, or other hematologic neoplasms. Mutations in MAPK pathway genes may occur in these diseases.
- R group. The paradigmatic member of this group is Rosai-Dorfman-Destombes disease, also known as sinus histiocytosis with massive lymphadenopathy. However, the R group also includes all of the other miscellaneous noncutaneous, non-Langerhans cell histiocytoses. Mutations in MAPK pathway genes may occur in these diseases.
- H group. This group contains the varieties of hemophagocytic lymphohistiocytosis and macrophage activation syndromes.

TABLE 155-1 CLASSIFICATION OF HISTIOCYTOSES AND MACROPHAGE/DENDRITIC CELL NEOPLASMS

L group	Langerhans cell histiocytosis (LCH) Indeterminate cell histiocytosis (ICH) Erdheim-Chester disease (ECD)
C group	Cutaneous non-Langerhans cell histiocytoses Xanthogranuloma (XG) family Juvenile xanthogranuloma (JXG) Adult xanthogranuloma (AXG) Solitary reticulohistiocytoma (SRH) Benign cephalic histiocytosis (BCH) Generalized disruptive histiocytosis (GEH) Progressive nodular histiocytosis (PNH) Xanthoma disseminatum (XD) Nonxanthogranuloma (non-XG) family Cutaneous Rosai-Dorfman-Destombes disease (RDD) Necrobiotic xanthogranuloma (NXG) Multicentric reticulohistiocytosis (MRH) Cutaneous non-Langerhans cell histiocytoses with major systemic involvement
R group	Familial Rosai-Dorfman-Destombes disease (RDD), also known as sinus histiocytosis with massive lymphadenopathy (SHML) Sporadic RDD Classical RDD Extranodal RDD RDD with neoplasia or immune disease Not otherwise classified
M group	Primary malignant histiocytoses Secondary malignant histiocytoses (associated with hematologic neoplasia) Subtypes: histiocytic, interdigitating, Langerhans, indeterminate
H group	Primary hemophagocytic lymphohistiocytosis (HLH) Secondary HLH HLH of unknown or uncertain origin

L GROUP LANGERHANS CELL HISTIOCYTOSIS

EPIDEMIOLOGY

Langerhans cell histiocytosis occurs predominantly in children (median age, 3.8 years) but is also seen in adults.[3] Its overall incidence is 2.6 cases per million child years for all children younger than 14 years of age but with a strong trend toward a higher incidence in younger children. There is a slight excess of cases in male patients (1.2 : 1). The incidence of high-risk Langerhans cell histiocytosis is lower in Blacks than in Whites and higher in Hispanics than in non-Hispanics. The incidence in adults has been estimated at 1 to 2 cases per million. Pulmonary Langerhans cell histiocytosis, which occurs primarily in adults, is strongly associated with a smoking history.

PATHOBIOLOGY

The cardinal feature of Langerhans cell histiocytoses is an accumulation of abnormal histiocytes having abundant pale cytoplasm and a single kidney- or coffee bean–shaped nucleus (Fig. 155-1A). All pathologic Langerhans cells express the surface marker CD1a (Fig. 155-1B), and most express CD207, a mannose-binding lectin also known as Langerin. A majority of cells contain intracellular organelles called Birbeck granules, which can be detected by electron microscopy and are composed of CD207 molecules. The lesions are commonly accompanied by a robust inflammatory infiltrate the quality of which may vary depending on the clinical subtype (e.g., abundant eosinophils in eosinophilic granuloma of bone) (see Clinical Manifestations).

Langerhans cell histiocytosis is a neoplastic disease with clonal cells, most of which carry somatic activating mutations in genes that encode members of the MAPK pathway. Specifically, 50 to 60% have mutated *BRAF* (predominantly, but not exclusively, the mutation that encodes the oncogenic variant BRAF V600E), and 25 to 30% have activating mutations of *MAP2K1*. All cases show evidence for activation of extracellular signal-regulated kinase (ERK), the target of this kinase pathway, and the remaining 10 to 25% of cases without *BRAF* or *MAP2K1* mutations have mutations in other genes that activate the pathway, including *ARAF* and *RAS* family members, or translocations resulting in fusion proteins that activate *BRAF*.[4]

Historically, Langerhans cell histiocytosis was acknowledged to be a disease of histiocytes, but because the origin of Langerhans cell histiocytes was unknown, the disease was called histiocytosis X. Langerhans histiocytosis cells express CD1a and CD207 and have Birbeck granules, all of which are characteristic of normal Langerhans cells. However, the profile of genes expressed by Langerhans histiocytosis cells is closer to that of myeloid precursor cells than mature Langerhans cells. In addition, *BRAF* mutations can be detected in hematopoietic stem cells of patients whose Langerhans histiocytosis cells have *BRAF* mutations, a finding suggesting that Langerhans cell histiocytosis is more properly viewed as a myeloid neoplasm in which myeloid precursors may partially differentiate in a direction that allows them to acquire attributes that are also characteristic of Langerhans cells.

CLINICAL MANIFESTATIONS

Langerhans cell histiocytoses may occur at any age and involve any organ. However, the disease is more common in children, and the organs most frequently affected include the following:

- Bone (80% of cases). Skeletal lesions may be asymptomatic or may be associated with tenderness and swelling. The most common locations (in descending order of frequency) are skull, pelvis, femur, ribs, humerus, mandible, and spine, where they appear as punched-out lytic lesions without sclerosis on radiographs (Fig. 155-1C). Resorption of alveolar bone can lead to the appearance of so-called "floating teeth."
- Skin (33% of cases). The rash may be intensely petechial and include scaly and encrusted papules (Fig. 155-1D and E). When skin involvement is the presenting manifestation, the rash may be confused with seborrheic dermatitis and "cradle cap" in infants.
- Hypothalamus and pituitary stalk (25% of cases). Pituitary involvement can lead to diabetes insipidus, which was historically observed to occur in

ABSTRACT

The histiocytoses are characterized by the accumulation in various organs of abnormal cells having features reminiscent of macrophages or dendritic cells. These diseases are heterogeneous in their clinical behaviors and outcomes, but recent advances in molecular genetics have led to a new nosology that divides histiocytic diseases into five categories: L Group: Langerhans cell histiocytosis (LCH), Erdheim-Chester disease, and indeterminate cell histiocytosis; C Group: non-Langerhans cell histiocytoses involving skin or mucosa and comprising both xanthogranuloma and nonxanthogranuloma subtypes; M Group: primary and secondary malignant histiocytoses; R Group: Rosai-Dorfman-Destombes disease and other noncutaneous, non-Langerhans cell histiocytoses; H Group: hemophagocytic lymphohistiocytosis and macrophage activation syndrome. The discovery of constitutive activation of the mitogen-activated protein kinase pathway, due largely to mutations in *BRAF* and *MAP2K1*, in Langerhans cell histiocytoses and Erdheim-Chester disease has led to clinical trials and observational studies describing major clinical responses to BRAF and MEK1 inhibitors. Targeted therapies based on gene mutations in other histiocytoses have also been effective. However, the role of these interventions in the standard treatment of these diseases awaits the results of ongoing clinical trials. In its familial form, hemophagocytic lymphohistiocytosis is associated with null germline mutations in genes encoding immune proteins such as perforin. Acquired hemophagocytic lymphohistiocytosis, triggered by malignancy, infection, or autoimmune disease, may be associated with hypomorphic alleles of these genes. Both forms are treated by immune suppression; hematopoietic stem cell transplantation may also be considered.

Revised classification of histiocytoses and neoplasms of the macrophage-dendritic cell lineages. *Blood*. 2016;127:2672-2781.)

25 to 50% of patients with Langerhans cell histiocytosis. With earlier diagnosis and effective chemotherapy, the contemporary incidence of diabetes insipidus has been reduced to 7 to 20%.

Involvement of the liver, spleen, bone marrow, or lungs occurs in 15% of cases; involvement of lymph nodes in 5 to 10%, and central nervous system (CNS; excluding pituitary) in 2 to 4%. Lung involvement is more frequent in adults than in children.

The clinical manifestations of Langerhans cell histiocytoses are extraordinarily diverse. However, some presentations were sufficiently stereotypic that they had been recognized as separate entities before the understanding that they are manifestations of the same disease. Importantly, the eponyms for these entities are no longer in use but are listed here to aid in understanding older literature:

- Hand-Schüller-Christian disease: triad of exophthalmos, diabetes insipidus, and bone lesions (especially cranial) in children; 15 to 40% of cases
- Letterer-Siwe disease (or Abt-Letterer-Siwe disease): multisystem disease involving skin, bone, lymph nodes, liver, and spleen in infants; poor prognosis
- Eosinophilic granuloma: bone only, often solitary; 60 to 80% of cases

TABLE 155-2 CLINICAL CLASSIFICATION OF LANGERHANS CELL HISTIOCYTOSIS*

CLINICAL GROUP	INVOLVED SYSTEM	INVOLVED ORGANS
1	Multisystem	Any risk organ†
2	Multisystem	≥2 organs *not including risk organs*
3	Single system • Multifocal‡ or special site§	≥2 lesions in one organ or in a special site§
—	Single system • Unifocal or localized	1 lesion in 1 organ

*Developed for the Langerhans Cell Histiocytosis-III (LCH-III) trial.
†Risk organs: bone marrow, liver, or spleen. (Lung is no longer classified as a risk organ.)
‡Multiple sites of involvement in a single organ system.
§Special sites confer increased risk of specific complications and include intracranial soft tissue extension or vertebral lesions with intraspinal soft tissue extension.

- Hashimoto-Pritzker disease (or congenital self-healing reticulohistiocytosis): self-limited skin involvement in newborns

The contemporary classification of Langerhans cell histiocytoses is based on clinical attributes that correlate with risk and therefore guide therapy. The two dimensions of risk are the number of organs involved (single system vs. multisystem disease) and the presence of disease in "risk organs" (defined as bone marrow, liver, or spleen; Table 155-2).

A late manifestation of Langerhans cell histiocytoses is neurodegeneration, which occurs in about 10% of surviving patients. Manifestations include ataxia, dysarthria, and dysmetria, along with neurocognitive decline and psychological difficulties. Magnetic resonance imaging (MRI) shows signal intensity changes in the cerebellar peduncles, basal ganglia, and pons. The clinical manifestations may wax and wane, but the disease is relentlessly progressive.

DIAGNOSIS

Because the clinical manifestations of Langerhans cell histiocytoses are nonspecific, clinicians must have a high index of suspicion in adult patients who present with a nonhealing seborrheic rash or solitary osteolytic lesion. In patients with diabetes insipidus, characteristic infiltration of the pituitary stalk may be seen on MRI. Pulmonary Langerhans cell histiocytoses should be considered in young smokers with dyspnea or a nonproductive cough whose plain chest radiographs show diffuse bilateral reticulonodular disease in the middle and upper lung zones. Computed tomography (CT) may show nodules or cysts.

Tissue analysis is mandatory. Histopathologic examination shows an infiltrate of histiocytic cells with pale cytoplasm and a single kidney- or coffee bean–shaped nucleus accompanied by varying numbers and types of inflammatory cells (see Fig. 155-1A). Eosinophils may be abundant. Definitive diagnosis requires a demonstration that the histiocytes stain for CD1a (see Fig. 155-1B). Positive staining for CD207 may further support the diagnosis of Langerhans cell histiocytosis. Electron microscopic examination for Birbeck granules has been supplanted by CD207 staining.

TREATMENT

Treatment strategies are evolving rapidly based on molecular testing, but decisions about specific therapies and their intensity have historically been driven by risk stratification. For example, patients with single system disease without organ dysfunction have an excellent prognosis and can be treated with local therapy (e.g., surgical curettage or radiation) or simply monitored and treated when symptomatic. More extensive disease requires systemic therapy, which typically begins with vinblastine and prednisone under expert supervision. Prolonging treatment in patients with multisystem disease decreases the risk of relapse from 54 to 37%. Thus, current standard of care for multisystem disease is vinblastine and prednisone induction followed by 12 months of continued therapy. Adding etoposide to the induction therapy may benefit patients with risk organ involvement.

Various approaches are available for relapsed or recurrent Langerhans cell histiocytosis, referred to historically as "reactivation," which occurs in 20 to 50% of patients. These patients can be placed into low-risk and high-risk categories. Low-risk patients are those who initially had low-risk multisystem Langerhans cell histiocytosis (i.e., no risk organ involvement or multifocal bone disease). Responses to a variety of second-line therapies have been documented, including 6-mercaptopurine and methotrexate, indomethacin, bisphosphonates, and nucleoside analogues such as cladribine, cytarabine, and clofarabine. High-risk patients are those who had risk organ involvement at presentation or showed a poor response to first-line treatment. Cladribine[5] and high-dose cytarabine may be effective in this setting, as is hematopoietic stem cell transplantation, but mortality is still significant.

The discovery of activating mutations in genes encoding MAPK pathway components has led to the use of rapidly advancing fibrosarcoma (RAF) and MAP kinase/ERK kinase 1 (MEK1) inhibitors, primarily in the relapsed setting.[6] In general, patients carrying sensitive mutations in *BRAF* or *MAP2K1*, including heavily pretreated patients, show remarkable responses to inhibitors of RAF (e.g., vemurafenib and dabrafenib), or MEK1 (e.g., cobimetinib, which has been approved by the FDA for use in patients with histiocytic neoplasms that do not carry the mutation encoding BRAF V600E). Optimal dosing has not yet been explored in a clinical trial, and treatment has generally been devised based on efficacy in other diseases. Most reports indicate that patients continue to respond to these inhibitors for as long as they are treated and have relapses when treatment is discontinued. Therefore, despite the remarkable efficacy of these agents, the roles that these inhibitors may play in curative or first-line treatment of Langerhans cell histiocytoses are currently unclear.

For adults with pulmonary Langerhans cell histiocytosis, smoking cessation is usually sufficient treatment. If not, these patients may be treated with corticosteroids. Patients with refractory cases may require lung transplantation.

PROGNOSIS

Outcomes in single system and low-risk disease are quite good. Overall survival for single system disease is more than 99%, with a relapse rate of 18%. In low-risk multisystem disease 5-year overall survival is 99% despite a 40 to 50% cumulative rate of relapse. Nonetheless, morbidities associated with the initial site of disease, especially orthopedic problems, may be long standing and significant. Patients with multisystem high-risk disease have an 84% 5-year overall survival with a 27% relapse rate in Langerhans cell histiocytosis-III. Failure to respond to initial therapy carries a dismal prognosis. Neurodegeneration may appear in up to 10% of patients several years after otherwise successful treatment and in the absence of active histiocytic disease. Sclerosing cholangitis (Chapter 141) may lead to long-term morbidity. The risk of developing leukemia or lymphoma is also higher than in the general population.[7]

ERDHEIM-CHESTER DISEASE

EPIDEMIOLOGY

Erdheim-Chester disease is extremely rare. Fewer than 1000 cases have been reported, and its precise incidence and prevalence are unknown. In contrast to Langerhans cell histiocytosis, Erdheim-Chester disease occurs primarily in adults between 40 and 70 years of age (mean age at diagnosis of 53 years),[8] although it may occur in children and infants. Male patients outnumber female patients by a ratio of nearly 3:1.

PATHOBIOLOGY

Histopathologic examination of lesions shows infiltration by foamy mononuclear histiocytes often accompanied by fibrosis and inflammation involving lymphocytes, neutrophils, or plasma cells. Occasional multinucleated giant cells may be observed. Because the histiocytes stain for CD68 and CD163, and not for CD1a, Erdheim-Chester disease histiocytes are thought to derive from the monocyte-macrophage lineage. Although these characteristics distinguish Erdheim-Chester disease from Langerhans cell histiocytosis, 20% of patients with Erdheim-Chester disease have concurrent Langerhans cell histiocytosis.

As in Langerhans cell histiocytosis, about 50% of patients with Erdheim-Chester disease have somatic mutations encoding BRAF V600E. Essentially all remaining patients have other genetic variants that activate the MAPK pathway, including mutations in *MAP2K1*, *ARAF*, *KRAS*, and *NRAS*, as well as gene fusions that activate *BRAF*, *ALK*, and *NTRK*. Mutations in *PIK3CA* have been observed and may co-occur with *BRAF* mutations.

CLINICAL MANIFESTATIONS

Histiocytic infiltration of bone occurs in nearly all patients, manifesting as symmetrical cortical sclerosis of diaphyseal and metaphyseal areas of long bones, often in the lower extremities (Fig. 155-1G). Patients may complain of mild juxta-articular pain but may also be asymptomatic in the presence of radiographic disease. Osteosclerosis of facial bones or other bones of the skull may also occur. CT or MRI may be necessary to detect lesions not seen on plain radiographs.

Cardiovascular involvement by fibrosis occurs in the majority of patients, may manifest as valvular abnormalities, conduction defects, or periaortic coating, and is one of the main causes of morbidity and mortality in Erdheim-Chester

disease. Similar fibrosis may occur in the retroperitoneum, encircling the kidneys and leading to a progressive obstructive nephropathy. About 50% of patients with Erdheim-Chester disease have pulmonary disease involving the pleura, parenchyma, or both. About 40% of patients have CNS disease, including pituitary involvement leading to diabetes insipidus and mass lesions in various parts of the brain. CNS involvement portends a worse outcome. Cognitive impairment and behavioral changes may also occur in the absence of MRI-documented infiltration or masses, although they may be associated with gray matter volume loss. Cutaneous disease occurs in about 25% of patients and usually manifests as xanthelasma, most frequently involving the eyelids (Fig. 155-1F).

DIAGNOSIS

Diagnosis must be made by histologic examination of involved sites, preferably osteosclerotic bone. Because genetic analysis for mutations in MAPK pathway genes informs clinical care and because decalcification for histologic examination may preclude such analysis, sufficient material must be collected and processed separately for both histologic and genetic testing. Absence of CD1a or CD207 staining will distinguish Erdheim-Chester disease from Langerhans cell histiocytosis. However, 20% of patients with Erdheim-Chester disease have concurrent Langerhans cell histiocytosis. Clinical manifestations of Erdheim-Chester disease may be confused with those of Paget disease or POEMS (polyneuropathy, organomegaly, endocrinopathy, myeloma protein, and skin changes) syndrome (Chapter 173), but the histopathologic picture of these disorders is distinct. Juvenile xanthogranuloma is a histiocytic disease of the C group (see later), and its histopathologic features are very similar to those of Erdheim-Chester disease. However, juvenile xanthogranuloma typically occurs in young children and only rarely involves extracutaneous sites. When juvenile xanthogranuloma is disseminated, lesional cells may harbor activating mutations in genes of the MAPK pathway, which is reminiscent of Erdheim-Chester disease and places this form of juvenile xanthogranuloma in the L group.

When the tissue diagnosis of Erdheim-Chester disease is confirmed, the extent of disease should be determined. A full endocrine evaluation should be performed to assess pituitary involvement, and imaging studies should include long bones, skull, and pelvis, as well as CT or MRI evaluation of the brain, the full length of the aorta, and the retroperitoneum. These studies may reveal characteristic periaortic thickening ("coated" aorta) and retroperitoneal fibrosis ("hairy kidneys"). Fluorine-18–radiolabeled fluorodeoxyglucose uptake demonstrated by positron emission tomography has been reported to provide high specificity in the setting of osteosclerosis (Fig. 155-1G). The presence of cardiac conduction abnormalities should be evaluated by electrocardiography. Macrophage-like cells that stain for S100 and show emperipolesis may be seen histologically and could suggest a diagnosis of Rosai-Dorfman-Destombes disease, but the clinical presentation of Erdheim-Chester disease is distinct from that of Rosai-Dorfman-Destombes disease (see later).

TREATMENT

Because most cases of Erdheim-Chester disease are indolent, asymptomatic patients who have no CNS disease may be followed without treatment.[9] If patients have CNS disease or develop troublesome symptoms, systemic treatment is warranted. The nearly universal presence of mutations in genes encoding components of the MAPK pathway in this disorder has moved targeted therapies to the forefront. A basket trial of the RAF inhibitor vemurafenib, given to patients with a variety of diseases carrying a somatic mutation encoding BRAF V600E and including several cases of Erdheim-Chester disease, resulted in prolonged responses in 6 of 18 patients. Thus RAF inhibitors may be administered under expert supervision to patients whose disease carries activating mutations in *BRAF* or *ARAF*. Patients without these mutations may be treated with the MEK inhibitor cobimetinib which the FDA has approved for treating BRAF V600E-negative Erdheim-Chester disease.

If targeted therapies cannot be used, treatment with interferon (IFN) alfa (conventional or pegylated) is recommended because of a suggestion of survival benefit in a retrospective analysis. For patients in whom IFN treatment fails, cladribine or cyclophosphamide may produce responses. Glucocorticoids, interleukin-1 receptor (IL-1R) antagonists, and anti-TNF agents may also have activity. Radiotherapy may provide relief of local symptoms.

PROGNOSIS

Although therapies targeted against BRAF V600E or MEK1 produce impressive symptomatic and radiographic responses in most patients with Erdheim-Chester disease, the impact of these drugs on survival is currently unknown. In one small study of patients treated with IFN-alfa, 1- and 5-year overall survival rates were 93 and 41%, respectively, versus 86 and 28% in patients who did not receive interferon.

INDETERMINATE CELL HISTIOCYTOSIS

Indeterminate cell histiocytosis is an exceedingly rare disease that may manifest as a cutaneous eruption mimicking Langerhans cell histiocytosis, although some cases may involve lymph nodes only. It occurs in adults and may predominantly affect women, although no rigorous epidemiologic analyses have been performed. Histologic analysis of lesions shows a nonepidermotropic infiltration of histiocytes that may stain for CD1a, similar to Langerhans cell histiocytosis, but do not express CD207. One report describes a case with a somatic mutation encoding BRAF V600E and may support the notion that indeterminate cell histiocytosis is related to Langerhans cell histiocytosis. However, another report collected four cases, three of which showed the same *ETV3-NCOA2* gene fusion. Although the pathogenic relevance of this translocation is unknown, its recurrent appearance in indeterminate cell histiocytosis and its absence from Langerhans cell histiocytoses indicate that these are distinct entities.

C GROUP

These non-Langerhans cell histiocytoses are divided into those that are predominantly cutaneous versus those that have a significant systemic component. Each group is further divided into the xanthogranuloma and nonxanthogranuloma categories.

XANTHOGRANULOMA FAMILY

EPIDEMIOLOGY

This group comprises several diseases that are distinguished primarily on the basis of clinical presentation: patient age, anatomic site of involvement, and whether lesions are solitary, multiple, or disseminated. Juvenile xanthogranuloma is the most commonly occurring non-Langerhans cell histiocytosis. Although its published prevalence is 0.5% of pediatric tumors, the benign nature of juvenile xanthogranuloma likely leads to underreporting. A slight excess of cases in female patients has been observed (1.4:1).

PATHOBIOLOGY

Lesions contain a dermal infiltrate that includes histiocytes, occasional multinucleated giant cells that may have the features of Touton cells, and nonspecific inflammatory cells. Regressing lesions show replacement by fibrous tissue. Histiocytes stain for CD68, CD14, CD163, factor XIIIa, and fascin; S100 staining may be absent or variable, and the cells do not stain for CD1a or CD207.

Juvenile xanthogranuloma may occur in association with neurofibromatosis type 1, although the relationship between genetic abnormalities in NF1 and JXG is unknown. Mutations involving *NRAS*, *KRAS*, *BRAF*, *ARAF*, *MAP2K1*, and *MAPK1* have been reported, as well as activating RNF11/BRAF and MRC1/PDGFRB fusions. Mutations in *PIK3CD* have also been reported. To date, MAPK pathway mutations have been described only in disseminated and not cutaneous cases. Because of the phenotypic similarities between disseminated JXG and Erdheim-Chester disease, and because of the presence of mutations in MAPK genes in both, disseminated juvenile xanthogranuloma has been classified in the L group. Cutaneous juvenile xanthogranuloma remains in the C group.

CLINICAL MANIFESTATIONS

Juvenile xanthogranuloma is a benign disease in which a variable number of small (<2.0-cm) yellow-red skin nodules appear most commonly on the head, neck, or upper trunk, although they may occur anywhere. About 70% of lesions are solitary. Systemic disease occurs rarely and may involve liver, lung, spleen, lymph nodes, bone, and gastrointestinal tract. Both cutaneous and systemic lesions generally resolve spontaneously within a few months or years, with no clinically significant sequelae. Some cases of disseminated juvenile xanthogranuloma in newborns or juvenile xanthogranuloma producing symptoms may require treatment.

Xanthoma disseminatum is also in the xanthogranuloma family and manifests as a cutaneous eruption of brown papules or nodules on flexor and periorbital areas. It involves mucosal surfaces and has a significant visceral component. Xanthoma disseminatum primarily affects young adult men and has a chronic clinical course that may include diabetes insipidus.

DIAGNOSIS

The clinical appearance of cutaneous xanthogranuloma may be sufficiently characteristic that a diagnosis can be made by observation alone. Biopsy and

immune staining may be required for ambiguous cases. Xanthogranuloma histiocytes stain for CD68, CD163, factor XIIIa, and fascin and do not stain for CD1a, CD207, and, generally, S100. Differential diagnosis includes the following: Langerhans cell histiocytosis, which can be distinguished by immune staining; papular xanthoma, the lesions of which contain more foam cells and fewer giant cells than xanthogranuloma; eruptive xanthoma, generally in hypertriglyceridemic adults; Spitz nevi; mastocytoma; and dermatofibroma.

TREATMENT

Patients with cutaneous juvenile xanthogranuloma may be observed without treatment. Patients with ocular involvement by juvenile xanthogranuloma or xanthoma disseminatum should be referred to an ophthalmologist for evaluation. Symptomatic visceral involvement may be treated, if necessary, with surgical excision, radiation therapy, or chemotherapy under expert supervision. Chemotherapeutic regimens used for Langerhans cell histiocytes may be effective in this setting.

PROGNOSIS

Cutaneous and visceral xanthogranuloma lesions spontaneously resolve, and the overall prognosis is excellent. Treatment outcomes for symptomatic visceral lesions are also good. Fatalities may occur rarely in infants with extensive hepatic involvement or CNS disease.

NONXANTHOGRANULOMA FAMILY

EPIDEMIOLOGY

Necrobiotic xanthogranuloma occurs in adults (average age of onset is in the sixth decade) and is accompanied by monoclonal gammopathy in 80% of patients.[10] There is no sex predilection. Multicentric reticulohistiocytosis is a disease of women in their 50s and 60s.[11] Rosai-Dorfman-Destombes disease may rarely be confined to the skin and in this manifestation should be considered a nonxanthogranuloma group C disease.

PATHOBIOLOGY

The pathobiology of necrobiotic xanthogranuloma is not understood, but its association with paraproteinemias has suggested that it may be a histiocytic reaction to the deposition of immunoglobulins. Histopathologic examination shows histiocytic xanthogranulomas with bands of necrosis in the dermis, accompanied by giant cells that may have a characteristic morphology for this disease. Lymphoid nodules and plasma cells may be seen.

One fourth of patients with multicentric reticulohistiocytosis have an underlying malignancy, thus raising the possibility that this is a paraneoplastic syndrome. However, no pathogenetic mechanism has been identified. Associated malignancies include breast and gastric cancers, as well as hematologic neoplasms.

CLINICAL MANIFESTATIONS

The cutaneous lesions of necrobiotic xanthogranuloma are discolored and indurated papules and nodules that may coalesce to form plaques, the centers of which may be atrophic. Periorbital areas are the most common site of involvement, but lesions may occur elsewhere on the face, trunk, arms, legs, and genitalia. The most common site of extracutaneous involvement is the eye and can manifest as uveitis or scleritis. Visceral involvement may also occur in a variety of sites but most commonly in the respiratory tract or cardiac structures.

The cutaneous lesions of multicentric reticulohistiocytosis are discolored papules that appear predominantly on the face, hands, forearms, and ears. The oral or nasal mucosa may also be involved. Periungual lesions may have a characteristic "coral bead" appearance. Patients with multicentric reticulohistiocytosis have a rapidly progressive destructive polyarthritis with systemic symptoms such as fever and weight loss.

DIAGNOSIS

Periorbital yellowish plaques with associated erythema and central atrophy or telangiectasias are highly suggestive of necrobiotic xanthogranuloma. Skin biopsy should be performed to confirm the diagnosis. Serum and urine electrophoresis should be performed to test for the presence of monoclonal gammopathy, and further hematologic work-up should be dictated by the results. Imaging of the chest, abdomen, and pelvis should be performed to assess visceral disease. The periorbital lesions of necrobiotic xanthogranuloma are distinguished from xanthelasmas or plane xanthomas by the former's larger size, induration, and erythema. Ocular involvement may be documented by conjunctival biopsy. Necrobiotic xanthogranuloma should also be distinguished from necrobiosis lipoidica, which occurs in patients with diabetes mellitus and has a histopathologic picture distinct from that of necrobiotic xanthogranuloma.

Histopathologic examination of multicentric reticulohistiocytosis shows frequent multinucleated giant cells and macrophages with eosinophilic cytoplasm. Multicentric reticulohistiocytosis may be reminiscent of fibroblastic rheumatism, although skin lesions in the latter are characterized histologically by fibrosis.

TREATMENT

Unlike xanthogranuloma, necrobiotic xanthogranuloma requires treatment because it does not spontaneously resolve and can produce disfiguring sequelae. No rigorous studies have identified an ideal treatment. Case reports suggest that alkylators such as chlorambucil or melphalan, with or without steroids, may be effective first-line therapy under expert supervision. Intravenous immunoglobulin has been used as second-line therapy, and lenalidomide has been used in patients with monoclonal gammopathy even in the absence of clinically documented multiple myeloma. Treatment of multicentric reticulohistiocytosis should be directed toward the underlying neoplasm if present.

PROGNOSIS

Scarring and ulceration may be common sequelae of cutaneous necrobiotic xanthogranuloma lesions. Patients with necrobiotic xanthogranuloma have an increased risk of developing hematologic malignancies and should be monitored. Treatment of the underlying neoplasm may not lead to resolution of multicentric reticulohistiocytosis.

R GROUP

The R group is composed primarily of the various manifestations of Rosai-Dorfman-Destombes disease, also known as sinus histiocytosis with massive lymphadenopathy.

EPIDEMIOLOGY

Sporadic Rosai-Dorfman-Destombes is a rare disease that occurs more commonly in children and young adults, with a peak incidence in the second and third decades. Overall prevalence is 5 per 100,000. The disease occurs more frequently in males and in individuals of African ancestry. Rosai-Dorfman-Destombes occurs in the lymph nodes of 20% of patients with H syndrome, which is associated with mutation in the *SLC29A3* gene. Nodal involvement also occurs in 41% of patients with autoimmune lymphoproliferative syndrome (ALPS) type Ia in which germline mutations affect *TNFRSF6*, which encodes Fas.

PATHOBIOLOGY

Nodal Rosai-Dorfman-Destombes is characterized by an accumulation in lymph node sinuses of large, polyclonal histiocytes with hypochromatic nuclei and pale cytoplasm, often showing emperipolesis (the presence of an intact cell within the cytoplasm of another cell). The histiocytes express macrophage markers, including S100, CD68, CD14, HLA-DR, and CD163, and do not express CD1a or CD207. Cortical regions of involved lymph nodes often have abundant plasma cells and activated B lymphocytes. Histiocytes may also accumulate in extranodal sites accompanied by plasma cells. The plasma cells are often immunoglobulin 4 (IgG4) positive. In some cases, histiocytes may harbor somatic mutations in MAPK pathway genes, *NRAS*, *KRAS*, *BRAF*, *ARAF*, and *MAP2K1*, suggesting that a subset of Rosai-Dorfman-Destombes disease may be associated with oncogenic driver mutations.

CLINICAL MANIFESTATIONS

Patients with nodal Rosai-Dorfman-Destombes present with nontender, massively enlarged cervical lymphadenopathy along with systemic inflammatory signs such as fever, leukocytosis, elevated erythrocyte sedimentation rate, and a polyclonal hypergammaglobulinemia. Nasal or tracheal obstruction may occur. Other involved nodal sites may include axilla, mediastinum, retroperitoneum, and inguinal regions. Extranodal involvement occurs in 43% of sporadic Rosai-Dorfman-Destombes cases, most commonly skin, nasal cavity, retro-orbital tissue, dura, bone, and soft tissue.

DIAGNOSIS

Diagnosis of Rosai-Dorfman-Destombes requires histopathologic examination of involved lymph nodes or extranodal tissues. The immunohistochemical staining pattern of the characteristic histiocytes is described earlier.

Rosai-Dorfman-Destombes disease can be distinguished from Langerhans cell histiocytosis by the absence of CD1a or CD207 staining. In cases of cutaneous involvement, differentiation from juvenile xanthogranuloma may be difficult. Intracranial Rosai-Dorfman-Destombes may have the radiographic appearance of meningioma, but characteristic cells may be seen in cerebrospinal fluid. Frequent IgG4-positive plasma cells in this disease may also raise a suspicion of IgG4-related disease (also known as hyper-IgG4 syndrome), although the clinical manifestations are distinct.

TREATMENT

Sporadic Rosai-Dorfman-Destombes disease generally has a favorable outcome and may resolve spontaneously over months to years. Symptomatic disease may be treated with corticosteroids, clofarabine, or radiation therapy under expert supervision. KRAS- or MEK-variant disease may respond to cobimetinib under expert oversight.[12]

PROGNOSIS

The prognosis of sporadic Rosai-Dorfman-Destombes is generally favorable.

M GROUP

The M group consists of malignant histiocytoses, which can be primary or can occur in association with other neoplasms.

EPIDEMIOLOGY

Malignant histiocytosis is rare, and its true incidence is unknown. It is a disease of adults, with a median age of diagnosis for the histiocytic sarcoma subtype in the mid-40s to mid-50s, and no sex imbalance. Secondary malignant histiocytosis may occur in the context of hematologic diseases such as acute lymphoblastic leukemia (but not acute myeloid leukemia), chronic lymphocytic leukemia, hairy cell leukemia, myelodysplastic syndrome, chronic myelomonocytic leukemia, follicular lymphoma, mediastinal germ cell tumors, and Langerhans cell histiocytosis.

PATHOBIOLOGY

Malignant histiocytosis cells are anaplastic and have frequent mitotic figures and atypical mitoses. Cells do not stain for epithelial markers such as keratins and epithelial membrane antigen (EMA), melanoma antigens such as melan-A and HMB45, B- and T-lymphocyte markers, and follicular dendritic cell markers. Malignant histiocytosis cells must express at least two of the histiocytic or dendritic cell markers CD68, CD163, CD4, or lysozyme and not express other histiocytosis markers such as S100, CD1a, or CD207. Malignant histiocytosis may manifest with various cellular phenotypes that are reminiscent of specific histiocytic cell types, and some pathologists have classified these as histiocytic, interdigitating dendritic cell, Langerhans cell, or indeterminate cell sarcomas. Recent recommendations suggest that the term *malignant histiocytosis* should be applied to the entire family of diseases and that the cellular phenotypes should be considered subtypes. In secondary malignant histiocytosis, clonal immunoglobulin rearrangements, translocations, or somatic mutations may appear both in the malignant histiocytosis cells and the cells of the underlying malignancy, a finding suggesting an evolutionary relationship between the two diseases.

CLINICAL MANIFESTATIONS

Patients may present with symptomatic mass lesions that can be accompanied by fever and weight loss. However, some lesions may be discovered incidentally through imaging studies. Disease may be unifocal or multifocal and can involve any organ, but malignant histiocytosis most commonly manifests in the intestinal tract, skin, or soft tissue. Malignant histiocytosis tumors generally progress rapidly.

DIAGNOSIS

Diagnosis depends on the presence of the histopathologic features described earlier. Other histiocytic or dendritic cell disorders such as Langerhans cell histiocytosis or hemophagocytic lymphohistiocytosis must be excluded. Malignant histiocytosis must also be distinguished from myeloid sarcomas, which are soft tissue collections of myeloid leukemia cells that are identical to leukemia cells in the circulation or bone marrow. Most challenging may be distinguishing the anaplastic cells of malignant histiocytosis from other aggressive malignancies such as diffuse large cell lymphoma, metastatic melanoma, and some metastatic carcinomas. Immunohistochemical staining patterns are useful to rule out these disorders.

TREATMENT

There is no standard of care for malignant histiocytosis. Depending on the sites of disease, effective approaches could include surgery, radiation therapy, or systemic chemotherapy, particularly regimens developed for aggressive lymphomas under expert supervision. A response to an RAF inhibitor in a histiocytic sarcoma carrying a BRAF V600E mutation has been reported, but this cannot be considered a standard therapeutic approach.

PROGNOSIS

A spectrum of outcomes can be seen in these patients, from spontaneous remission to recurrent and refractory disease. No markers have been described that reliably predict response to therapy.

H GROUP, INCLUDING HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

The H group comprises hemophagocytic lymphohistiocytosis, a disorder of immune hyperactivity that was originally described and characterized in infants and young children but is increasingly recognized as a disorder also seen in adults. In children, hemophagocytic lymphohistiocytosis is predominantly a congenital syndrome associated with homozygous genetic abnormalities that abolish the expression of key immune response genes necessary for normal T-cell and NK-cell responses (Chapter 231), although it may also be seen in association with certain infections and as a complication of systemic autoimmune disease. In adults, hemophagocytic lymphohistiocytosis is most commonly associated with lymphoid malignancy, but it also may be a complication of infection or autoimmune disease; in a subset of cases, no inciting abnormality can be found.[13]

EPIDEMIOLOGY

The estimated incidence of familial hemophagocytic lymphohistiocytosis is widely variable, reflecting both geographic variation and rate of successful detection. Estimates range from 1 to more than 200 in 300,000 births. Although it is a rare syndrome outside the pediatric population, the incidence of hemophagocytic lymphohistiocytosis in adults is impossible to estimate because it has been recognized as a syndrome occurring in adults only for the last 15 to 20 years. With increased recognition of the syndrome, it has become apparent that it is less rare than was previously appreciated. Hemophagocytic lymphohistiocytosis appears to be more common in China and Japan than it is in the West.

PATHOBIOLOGY

Hemophagocytic lymphohistiocytosis reflects an uncontrolled immune activation resulting from a failure of cytotoxic T-cell and NK-cell cytotoxicity. On recognition of antigen, these effector cells release perforin-containing cytolytic granules that contribute to lysis of the antigen-expressing target cell. Under normal conditions, target cell elimination limits antigen exposure, leading to downregulation of the immune response, termed *activation-induced cell death.* In familial hemophagocytic lymphohistiocytosis, however, homozygous null mutations in one of a series of genes involved in the synthesis, trafficking, and function of cytotoxic granules from cytotoxic immune cells, including *PRF1, UNC13D, STX11, STXBP2, RAB27A, LYST*, and *AP3B*, leads to inability to clear antigenic stimuli, thus causing a persistent and amplified immune response. The persistently activated cytotoxic T cells and NK cells release high levels of inflammatory cytokines, leading to macrophage activation, hemophagocytosis, and other manifestations of "cytokine storm." The inciting stimulus to the presentation of familial hemophagocytic lymphohistiocytosis is usually an infection, most frequently with Epstein-Barr virus (EBV). In children, secondary hemophagocytic lymphohistiocytosis may occur as a result of infection or autoimmune disease. In the setting of autoimmune disease, it is termed *macrophage activation syndrome.*

Hemophagocytic lymphohistiocytosis was nearly unrecognized as a disease that occurred in adults until the last 15 to 20 years. Since then it has become clear that, although rare, it is being increasingly diagnosed worldwide. It is not clear whether the increasing recognition of adult hemophagocytic lymphohistiocytosis reflects a higher incidence or greater ascertainment.

Most, if not all, adults with hemophagocytic lymphohistiocytosis are thought to have "secondary" or "acquired" hemophagocytic lymphohistiocytosis. The triggers of adult hemophagocytic lymphohistiocytosis include malignancy,

infection, and systemic autoimmune disease. Malignancy (especially lymphoma) is the trigger for hemophagocytic lymphohistiocytosis in more than one half of adult patients. The mechanism of acquired hemophagocytic lymphohistiocytosis is much less well understood, although the pattern of immune hyperactivity and cytokine excess is similar.

With the increasing recognition of hemophagocytic lymphohistiocytosis in adults, significant attention has focused on polymorphisms and potential heterozygous mutations in the familial hemophagocytic lymphohistiocytosis genes that may predispose patients to acquire hemophagocytic lymphohistiocytosis in the presence of other triggers. In the original study examining the presence of genetic mutations in familial hemophagocytic lymphohistiocytosis genes in samples from adults suspected of having hemophagocytic lymphohistiocytosis, about 15% were found to have presumed hypomorphic alleles in the familial hemophagocytic lymphohistiocytosis genes. The most common mutation is in the perforin gene (*A92V*), and it is a polymorphism present in 5 to 8% of the general population. The effect of these mutations is unclear, although modeling suggests they may reduce the function of their cognate proteins, and some individuals have had detectable subtle abnormalities in NK-cell function. These mutations likely represent predisposing factors that are part of the pathogenesis of the disease in the setting of other triggers; however, the frequency of some of the mutations and their presence in asymptomatic family members suggest that they are not a driver of the disease.

CLINICAL MANIFESTATIONS

Familial hemophagocytic lymphohistiocytosis typically manifests in the first year of life, nearly always in the setting of infection, most commonly with Epstein-Barr virus. Children usually have prominent CNS symptoms, whereas this is much less frequent in adults. Adults may present with secondary hemophagocytic lymphohistiocytosis at any age. Patients frequently present with a fulminant picture of fever, cytopenias, and multiorgan failure, and they are often suspected of having septic shock. Because the inciting event in hemophagocytic lymphohistiocytosis is most commonly an infection, treatment of the infection may improve the patient's clinical status. However, recrudescence of symptoms is common because once hemophagocytic lymphohistiocytosis is triggered it is usually not self-limited without directed intervention. As delineated later in the diagnostic criteria for hemophagocytic lymphohistiocytosis, fever and cytopenias are often accompanied by splenomegaly, coagulopathy, dyslipidemia, liver function abnormalities, and elevated serum ferritin. Bone marrow aspiration frequently, although not always, demonstrates hemophagocytosis. Many of the clinical features of hemophagocytic lymphohistiocytosis are nonspecific, and diagnosis may be delayed. As discussed in the next section, the diagnosis, especially in adults, may be challenging.

DIAGNOSIS

The diagnostic criteria for hemophagocytic lymphohistiocytosis (Table 155-3) are based on pediatric hemophagocytic lymphohistiocytosis, but they generally perform well in diagnosing the disease in adults.[14] Other diagnostic algorithms have been designed with the intent of improving diagnostic accuracy, especially in adults, but they probably add little to the ability to diagnose hemophagocytic lymphohistiocytosis in adult patients, except perhaps at initial presentation or when some specialized tests such as the soluble IL-2 receptor (sIL2r or sCD25) are unavailable.

TABLE 155-3 DIAGNOSTIC CRITERIA FOR HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

Molecular diagnosis of familial disease
OR
At least 5 of the following 8 criteria:
Fever
Cytopenia of ≥2 lineages
Splenomegaly
Hypertriglyceridemia and/or hypofibrinogenemia
Ferritin >500 ng/mL
Soluble CD25/sIL2r >2400 U/mL
Hemophagocytosis in bone marrow, spleen, or lymph nodes
Low or absent NK-cell activity

NK = natural killer; sIL2r = soluble interleukin-2 receptor.

The first critical step in the diagnosis of hemophagocytic lymphohistiocytosis is to consider the diagnosis because until recently it was rarely entertained in adult patients. In considering the diagnosis, a thorough history should include details regarding recent infections, history of autoimmune disease, underlying malignancy, and underlying immune disorders. Testing should include complete blood count, full metabolic panel, triglycerides, fibrinogen, ferritin, and sIL2r where available. Thorough evaluation for bacterial, parasitic, mycobacterial, and fungal infection should be performed, as well as evaluation for viral infection to include both serology and viral titers for Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus, influenza, hepatitis B and C, herpes simplex virus, varicella-zoster virus, parvovirus, adenovirus, and human herpesvirus-8. Patients should be evaluated for evidence of systemic autoimmune disease. Importantly, because lymphoma is a trigger of hemophagocytic lymphohistiocytosis in about half of adult patients, every effort should be made to find evidence for lymphoma. Patients should undergo marrow examination, and marrow samples should be sent for flow cytometry and T-cell gene rearrangement studies in addition to routine studies. When possible, full evaluation for lymphoma, including a positron emission tomographic (PET) scan, should be performed before initiation of therapy because therapy for hemophagocytic lymphohistiocytosis is likely to mask accompanying lymphoma and thereby impede its timely diagnosis.

Diagnosis of hemophagocytic lymphohistiocytosis requires demonstration of homozygous or compound heterozygous null mutations in familial hemophagocytic lymphohistiocytosis genes (seen in children) or fulfillment of five of eight criteria (see Table 155-3): fever, cytopenias, hypofibrinogenemia or hypertriglyceridemia, elevated ferritin, elevated soluble IL-2 receptor (sIL2r or sCD25), splenomegaly, hemophagocytosis in the bone marrow, and impaired NK-cell function. Because NK-cell function is highly variable outside of familial hemophagocytic lymphohistiocytosis and rarely tested, diagnosis in adults is usually made by satisfying five of the other seven criteria in Table 155-3.

Fever and cytopenias are universal findings in patients presenting with hemophagocytic lymphohistiocytosis. These signs are reflective of the exuberant secretion of inflammatory cytokines released by activated T and NK cells and macrophages, including IFN-γ, tumor necrosis factor-α, IL-2, IL-4, IL-6, and IL-10. Splenomegaly has been reported to occur in about half of adults with hemophagocytic lymphohistiocytosis, and its presence may reflect the duration of the illness before diagnosis. Hypertriglyceridemia and/or hypofibrinogenemia occur in at least 50% of adults with hemophagocytic lymphohistiocytosis. Elevated liver function test results, although not a criterion for the diagnosis, are seen in almost all patients.

Hyperferritinemia has often been considered the hallmark of hemophagocytic lymphohistiocytosis and macrophage activation syndrome. In children, a serum ferritin level higher than 10,000 mg/dL has been demonstrated to be more than 90% sensitive and specific for hemophagocytic lymphohistiocytosis. However, in adults, ferritin is less powerful for establishing the diagnosis. Survey of a database of patients for elevated ferritin revealed that even with ferritin levels higher than 50,000 mg/dL, fewer than 20% of patients will have hemophagocytic lymphohistiocytosis; conversely, among adults diagnosed with hemophagocytic lymphohistiocytosis, the ferritin level ranges from 600 mg/dL to more than 50,000 mg/dL. Therefore, the negative predictive value of a normal ferritin result is high, but it is not a discerning marker for hemophagocytic lymphohistiocytosis in adults. Because hyperferritinemia is a nonspecific consequence of macrophage activation, it is also elevated in other chronic inflammatory conditions, hemolytic anemia, and renal failure, all of which are more common in adults than in children.

The soluble form of the IL-2 receptor (sIL2r, sCD25) is also elevated in hemophagocytic lymphohistiocytosis. The IL-2 receptor is widely expressed by lymphocytes, monocytes, eosinophils, and NK cells; is cleaved by macrophage gelatinase (MMP9) to release the soluble form of the receptor; and is a marker of immune activation in many inflammatory disorders. Although it is elevated in nearly all, if not all, patients with hemophagocytic lymphohistiocytosis, it is not a readily available test. However, it can be an extremely valuable diagnostic marker. In particular, in adults, it is usually extremely elevated in lymphoma-associated hemophagocytic lymphohistiocytosis because the malignant lymphoma cells themselves express high levels of IL2r. The ratio of sIL2r to ferritin can help distinguish lymphoma-associated hemophagocytic lymphohistiocytosis from other forms of hemophagocytic lymphohistiocytosis in adults: the ratio is usually less than 1 in the absence of malignancy and greater than 2 in the setting of lymphoma-associated hemophagocytic lymphohistiocytosis.

Hemophagocytosis is often a prominent feature of hemophagocytic lymphohistiocytosis, but it is neither sensitive nor specific for the diagnosis. In adults, hemophagocytosis is often prominent, but many other diagnoses are associated with hemophagocytosis (e.g., acute viral infections and hemolytic anemias).

Evaluation for genetic mutations in familial hemophagocytic lymphohistiocytosis genes may be helpful in later management, but it is not urgent for the initial evaluation.

TREATMENT

Therapy of hemophagocytic lymphohistiocytosis is aimed at suppressing the abnormal immune response, usually through a combination of immunosuppressive and targeted anti–T-cell therapy (Fig. 155-2).[15] Because there have been no large trials of therapy for adult hemophagocytic lymphohistiocytosis, most adults are treated with the HLH-94 protocol, which was studied in a large prospective trial for pediatric hemophagocytic lymphohistiocytosis (Table 155-4). This therapy entails dexamethasone and etoposide with an 8-week induction course under expert supervision. Children with neurologic symptoms receive intrathecal methotrexate, but it is rarely necessary in adults. Following completion of the 8-week course, patients can be put on maintenance therapy with the addition of calcineurin inhibitors to intermittent dexamethasone and etoposide, usually as a bridge to stem cell transplantation. An alternative is the modified HLH-2004 protocol (Table 155-4). Patients with significant liver dysfunction can have initial dose reduction of etoposide with dose increases as function improves. Renal failure may also require dose reduction. Treatment should not usually be withheld for cytopenias, which often reflect disease activity rather than drug toxicity. However, adults often do not tolerate the initial bi-weekly dosing of etoposide, and it is usual to hold at least one of the initial four doses, or start immediately with weekly dosing.

TABLE 155-4 HLH-94 AND HLH-2004 PROTOCOLS FOR TREATMENT OF HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS (HLH)

HLH-94 PROTOCOL

Initial Therapy for the First 8 Weeks:

- **Dexamethasone** at 10 mg/m^2 orally per day weeks 1-2; 5 mg/m^2 per day weeks 3-4; 2.5 mg/m^2 per day weeks 5-6; 1.25 mg/m^2 per day week 7; taper during week 8
- **Etoposide** at 150 mg/m^2 orally twice weekly for weeks 1-2; then once weekly
- **Intrathecal MTX (for children with neurologic symptoms only)** at 12 mg per dose, given at weeks 3 and 4, with two additional doses at weeks 5 and 6 if progressive neurologic symptoms and/or abnormal CSF not improved after 2 weeks

Continuation Therapy/HSCT:

- **Dexamethasone** at 10 mg/m^2 per day for 3 days, given every 2nd week
- **Etoposide** 150 mg/m^2 × 1 in alternate weeks
- **Cyclosporine A** beginning at week 9, dosing aimed at trough level of 200 µg/L

HLH-2004 PROTOCOL

Initial Therapy for the First 8 Weeks:

Same as HLH-94 Protocol, except (1) cyclosporine A beginning at day 1 and continuing into the Continuation phase. Recommend starting cyclosporine A at a daily dose of 6 mg/kg, with dosing aimed at trough level of 200 µg/L; and (2) adding prednisone to MTX for intrathecal injections (for children with neurologic symptoms only)

Continuation Therapy/HSCT as Soon as an Accepted Donor Is Identified

CSF = cerebrospinal fluid; MTX = methotrexate.

Modified from Bergsten E, Horne A, Aricó M, et al. Confirmed efficacy of etoposide and dexamethasone in HLH treatment: long-term results of the cooperative HLH-2004 study. *Blood*. 2017;130:2728-2738.

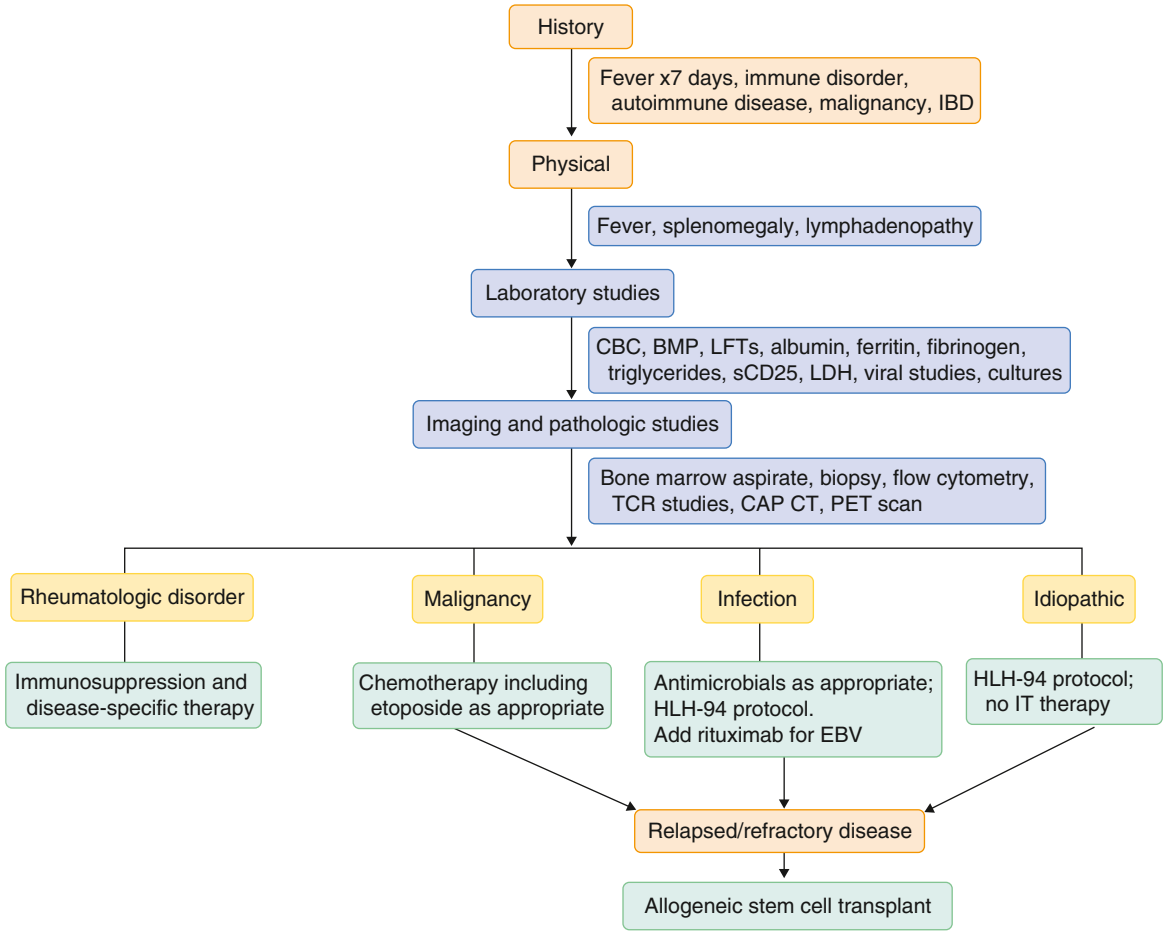

FIGURE 155-2. Approach to diagnosis and treatment of adult hemophagocytic lymphohistiocytosis (HLH). BMP = basic metabolic panel; CAP CT = chest, abdomen, pelvis computed tomography; CBC = complete blood count; EBV = Epstein-Barr virus; HLH-94 protocol (see text and grade A reference A2); IBD = inflammatory bowel disease; IT = immunotherapy; LDH = lactate dehydrogenase; LFTs = liver function tests; PET = positron emission tomography; sCD25 = soluble CD25; TCR = T-cell receptor.

Therapy is tailored to the underlying trigger for the syndrome. In patients with malignancy-associated hemophagocytic lymphohistiocytosis, treatment for the malignancy should be initiated immediately. Because most malignancy-associated hemophagocytic lymphohistiocytosis accompanies a lymphoma, therapy with an etoposide-containing regimen is recommended, and steroid therapy should be continued until the hemophagocytic lymphohistiocytosis has resolved. Epstein-Barr virus-related hemophagocytic lymphohistiocytosis is driven by viral infection of T lymphocytes, so treatment with the HLH-94 protocol should be administered without delay. In addition, rituximab is recommended to clear the B-cell reservoir of virus. Patients with no clear precipitating trigger ("idiopathic hemophagocytic lymphohistiocytosis") should receive the HLH-94 protocol with continued evaluation for underlying undiagnosed lymphoma or infection.

The one exception to the recommendation for cytotoxic therapy for adult hemophagocytic lymphohistiocytosis is for patients with macrophage activation syndrome. This subtype of hemophagocytic lymphohistiocytosis is often difficult to distinguish from an acute flare of the patient's underlying systemic autoimmune disease. Macrophage activation syndrome usually responds to intensification of immunosuppressive therapy for the primary disease and does not usually require cytotoxic therapy.

Patients who fail to respond to the HLH-94 protocol may receive salvage therapy with alemtuzumab, a monoclonal anti-CD52 antibody that destroys mature T cells, under expert supervision. This agent should be viewed as a bridge to stem cell transplant in eligible patients. In this setting, alemtuzumab has also been demonstrated to reduce the incidence of graft versus host disease (GVHD) after stem cell transplantation and is now incorporated into the conditioning regimen before stem cell transplantation for hemophagocytic lymphohistiocytosis.

The role of hematopoietic stem cell transplantation (HSCT) (Chapter 163) in hemophagocytic lymphohistiocytosis is evolving. Familial hemophagocytic lymphohistiocytosis is uniformly fatal without HSCT, but the necessity for other patients with HLH to undergo HSCT is less clear. In many children with infection-associated hemophagocytic lymphohistiocytosis, hemophagocytic lymphohistiocytosis resolves completely with HLH-94 therapy. The outcomes in adults are less clear, but adult patients who have refractory or relapsed disease or who have had life-threatening disease at presentation should be evaluated for transplantation. Patients must be in remission at the time of HSCT because patients with active hemophagocytic lymphohistiocytosis at the time of transplantation fare poorly and usually die of overwhelming GVHD. Outcomes are superior with reduced intensity conditioning. Successful HSCT is curative.

Novel therapies that may have an increasing role in the treatment of hemophagocytic lymphohistiocytosis include emapalumab and ruxolitinib. Emapalumab (1 mg/kg by intravenous infusion every 3-4 days, with dose increases up to 10 mg/kg based on clinical response and toxicity) is an FDA-approved antibody that targets IFN-γ and has been moderately effective for the treatment of refractory hemophagocytic lymphohistiocytosis in children.[16] It also may be useful for adults with hemophagocytic lymphohistiocytosis when combined with dexamethasone (5 to 10 mg/m^2) for the duration of treatment, although clinical studies in the adult population have not yet been performed. The Janus kinase 1/2 inhibitor ruxolitinib has been studied in early clinical trials and is not FDA approved for use in hemophagocytic lymphohistiocytosis, but it is a possible adjunct to therapy under expert supervision, especially in patients with intractable symptoms.

156 EOSINOPHILIC SYNDROMES

AMY D. KLION

DEFINITIONS

Eosinophils are terminally differentiated cells of the myeloid lineage that circulate in low numbers in the peripheral blood. Although normal ranges vary depending on the laboratory, blood eosinophilia is typically defined as an absolute eosinophil count of greater than 450/μL and hypereosinophilia as an absolute eosinophil count of 1500/μL or greater. Percentages of eosinophils in the total white blood count (WBC) can be misleading because they are affected by the relative numbers of neutrophils, which can be impacted by a number of factors (e.g., low neutrophil counts seen in certain racial/ethnic groups presumably due to polymorphisms in the Duffy antigen receptor [see Chapter 153] or the selective increase in neutrophils seen in response to glucocorticoids or bacterial infection). Tissue hypereosinophilia is loosely defined as extensive eosinophil infiltration in the opinion of the pathologist and may or may not be accompanied by blood eosinophilia. Consensus thresholds for tissue hypereosinophilia have not been defined, except for bone marrow eosinophilia (20% of nucleated cells) and eosinophilic esophagitis (≥15 eosinophils/high-power field).[1]

The hypereosinophilic syndrome can be defined by blood or tissue hypereosinophilia on at least two occasions with evidence of clinical manifestations attributable to the eosinophilia, regardless of the underlying etiology. This definition encompasses a number of clinical subtypes that differ in etiology and/or clinical manifestations and have prognostic and therapeutic implications (Table 156-1).[2] Hypereosinophilia or hypereosinophilic syndrome can be due to neoplastic or clonal proliferation of eosinophils (myeloid hypereosinophilia or hypereosinophilic syndrome), aberrant lymphocyte production of cytokines that promote eosinophilia (lymphoid hypereosinophilia or hypereosinophilic syndrome), inherited genetic abnormalities (familial hypereosinophilia or hypereosinophilic syndrome), or unknown causes (idiopathic hypereosinophilia or hypereosinophilic syndrome).[3,4] Overlap hypereosinophilic syndrome refers to eosinophilic disorders involving a single organ system, such as eosinophilic gastrointestinal disorders and eosinophilic fasciitis, or defined clinical entities, such as eosinophilic granulomatosis with polyangiitis (Chapter 249) or episodic angioedema and eosinophilia (Gleich syndrome), that overlap in clinical presentation with other subtypes of hypereosinophilic syndrome. Finally, secondary or associated hypereosinophilia or hypereosinophilic syndrome can complicate a wide variety of diseases and conditions, including helminth infection (Chapters 325 to 327), neoplasia, and drug hypersensitivity.

EPIDEMIOLOGY

Eosinophilia (absolute eosinophil count >450 eosinophils/μL) is common, occurring in 5 to 15% of the general population depending on the setting. The most frequent cause of mild to moderate eosinophilia worldwide is helminth infection, although atopic disease is the most likely culprit in industrialized settings. In contrast, hypereosinophilic syndrome (with the exception of some of the single-organ variants) is extremely rare, with an overall estimated prevalence of 0.3 to 6.3 per 100,000 in North America. The prevalence of eosinophilic esophagitis (Chapter 124) appears to be increasing, in keeping with an overall increase in the incidence of atopic disease, and has been estimated at 2.5 to 5 per 10,000 in the United States and Europe. Racial and ethnic differences have also been described.

PATHOBIOLOGY

Eosinophil Biology and Mediators of Tissue Damage

Eosinophils develop from pluripotent hematopoietic stem cells in the bone marrow (Chapter 142) under the influence of a complex array of transcription factors and cytokines, the most important of which is interleukin-5 (IL-5). Mature eosinophils are characterized by the presence of cytoplasmic granules that stain red with the acidic dye eosin. These granules contain four cationic proteins (major basic protein [MBP1], eosinophilic cationic protein [ECP], eosinophil-derived neurotoxin [EDN], and eosinophil peroxidase [EPO]) and a panoply of preformed cytokines and chemokines within a complex membranovesicular network. Release of granule proteins and mediators can occur in an indiscriminate way (through cytolysis or classic exocytosis) or selectively through a process called piecemeal degranulation.

Under homeostatic conditions, mature eosinophils are released into the blood, where they remain in the circulation for up to 36 hours before trafficking to the tissues. Data suggest that these "resident" eosinophils may play important regulatory roles in the maintenance of tissue integrity and cell-cell interactions. When eosinophils become activated, irrespective of the cause, they can cause tissue damage and other clinical manifestations through direct and indirect mechanisms. The latter include tissue deposition of cytotoxic eosinophil granule proteins and reactive oxygen intermediates, recruitment of inflammatory cells through the selective secretion of cytokines and chemokines, formation of lipid bodies with production of leukotrienes and other inflammatory mediators, and activation of mast cells, fibroblasts, and endothelial cells to promote fibrogenesis and thrombosis. Modulation of surface receptor expression and increased

AMY D. KLION

DEFINITIONS

Eosinophils are terminally differentiated cells of the myeloid lineage that circulate in low numbers in the peripheral blood. Although normal ranges vary depending on the laboratory, blood eosinophilia is typically defined as an absolute eosinophil count of greater than 450/μL and hypereosinophilia as an absolute eosinophil count of 1500/μL or greater. Percentages of eosinophils in the total white blood count (WBC) can be misleading because they are affected by the relative numbers of neutrophils, which can be impacted by a number of factors (e.g., low neutrophil counts seen in certain racial/ethnic groups presumably due to polymorphisms in the Duffy antigen receptor [see Chapter 153] or the selective increase in neutrophils seen in response to glucocorticoids or bacterial infection). Tissue hypereosinophilia is loosely defined as extensive eosinophil infiltration in the opinion of the pathologist and may or may not be accompanied by blood eosinophilia. Consensus thresholds for tissue hypereosinophilia have not been defined, except for bone marrow eosinophilia (20% of nucleated cells) and eosinophilic esophagitis (≥15 eosinophils/high-power field).[1]

The hypereosinophilic syndrome can be defined by blood or tissue hypereosinophilia on at least two occasions with evidence of clinical manifestations attributable to the eosinophilia, regardless of the underlying etiology. This definition encompasses a number of clinical subtypes that differ in etiology and/or clinical manifestations and have prognostic and therapeutic implications (Table 156-1).[2] Hypereosinophilia or hypereosinophilic syndrome can be due to neoplastic or clonal proliferation of eosinophils (myeloid hypereosinophilia or hypereosinophilic syndrome), aberrant lymphocyte production of cytokines that promote eosinophilia (lymphoid hypereosinophilia or hypereosinophilic syndrome), inherited genetic abnormalities (familial hypereosinophilia or hypereosinophilic syndrome), or unknown causes (idiopathic hypereosinophilia or hypereosinophilic syndrome).[3,4] Overlap hypereosinophilic syndrome refers to eosinophilic disorders involving a single organ system, such as eosinophilic gastrointestinal disorders and eosinophilic fasciitis, or defined clinical entities, such as eosinophilic granulomatosis with polyangiitis (Chapter 249) or episodic angioedema and eosinophilia (Gleich syndrome), that overlap in clinical presentation with other subtypes of hypereosinophilic syndrome. Finally, secondary or associated hypereosinophilia or hypereosinophilic syndrome can complicate a wide variety of diseases and conditions, including helminth infection (Chapters 325 to 327), neoplasia, and drug hypersensitivity.

EPIDEMIOLOGY

Eosinophilia (absolute eosinophil count >450 eosinophils/μL) is common, occurring in 5 to 15% of the general population depending on the setting. The most frequent cause of mild to moderate eosinophilia worldwide is helminth infection, although atopic disease is the most likely culprit in industrialized settings. In contrast, hypereosinophilic syndrome (with the exception of some of the single-organ variants) is extremely rare, with an overall estimated prevalence of 0.3 to 6.3 per 100,000 in North America. The prevalence of eosinophilic esophagitis (Chapter 124) appears to be increasing, in keeping with an overall increase in the incidence of atopic disease, and has been estimated at 2.5 to 5 per 10,000 in the United States and Europe. Racial and ethnic differences have also been described.

PATHOBIOLOGY

Eosinophil Biology and Mediators of Tissue Damage

Eosinophils develop from pluripotent hematopoietic stem cells in the bone marrow (Chapter 142) under the influence of a complex array of transcription factors and cytokines, the most important of which is interleukin-5 (IL-5). Mature eosinophils are characterized by the presence of cytoplasmic granules that stain red with the acidic dye eosin. These granules contain four cationic proteins (major basic protein [MBP1], eosinophilic cationic protein [ECP], eosinophil-derived neurotoxin [EDN], and eosinophil peroxidase [EPO]) and a panoply of preformed cytokines and chemokines within a complex membranovesicular network. Release of granule proteins and mediators can occur in an indiscriminate way (through cytolysis or classic exocytosis) or selectively through a process called piecemeal degranulation.

Under homeostatic conditions, mature eosinophils are released into the blood, where they remain in the circulation for up to 36 hours before trafficking to the tissues. Data suggest that these "resident" eosinophils may play important regulatory roles in the maintenance of tissue integrity and cell-cell interactions. When eosinophils become activated, irrespective of the cause, they can cause tissue damage and other clinical manifestations through direct and indirect mechanisms. The latter include tissue deposition of cytotoxic eosinophil granule proteins and reactive oxygen intermediates, recruitment of inflammatory cells through the selective secretion of cytokines and chemokines, formation of lipid bodies with production of leukotrienes and other inflammatory mediators, and activation of mast cells, fibroblasts, and endothelial cells to promote fibrogenesis and thrombosis. Modulation of surface receptor expression and increased

ABSTRACT

Eosinophils are terminally differentiated cells of the myeloid lineage that are primarily tissue based and circulate in low numbers in the blood of healthy individuals. Increased levels of blood eosinophils are associated with a wide variety of conditions, ranging from atopic disorders and helminth infections to rare hypereosinophilic syndromes. Since the clinical manifestations of eosinophilia are protean and can be very similar regardless of the underlying etiology, a careful history is essential to narrow the differential diagnosis. Treatment is guided by the acuity and severity of clinical manifestations and the most likely cause of the eosinophilia. Whereas glucocorticoids have been the mainstay of treatment for many eosinophilic disorders, the availability of therapies that directly target the eosinophils is rapidly changing the therapeutic paradigm.

TABLE 156-1 CLINICAL SUBTYPES OF HYPEREOSINOPHILIA/HYPEREOSINOPHILIC SYNDROMES

CLINICAL SUBTYPE	DEFINITION	EXAMPLES
Myeloid (clonal, neoplastic)	Presumed or proven primary neoplastic or clonal eosinophilia	*PDGFR*-associated myeloid neoplasms Chronic eosinophilic leukemia–not otherwise specified
Lymphocytic	Eosinophilia secondary to production of interleukin-5 or other eosinophil-promoting cytokines by aberrant and/or clonal lymphocytes	—
Familial	Hypereosinophilia in multiple generations	Autosomal dominant familial eosinophilia
Idiopathic	Unknown cause and exclusion of other clinical subtypes	—
Overlap	Clinically defined eosinophilic disorders, including those with single organ involvement, that overlap in clinical presentation with idiopathic or lymphocytic variant hypereosinophilic syndrome	Eosinophilic gastrointestinal disease Eosinophilic fasciitis Eosinophilic granulomatosis with polyangiitis Wells syndrome Episodic angioedema and eosinophilia
Secondary (associated)	Eosinophilia in the setting of a distinct diagnosis in which eosinophilia has been described in a subset of patients	See Table 156-2
Hypereosinophilia of unknown significance	Asymptomatic hypereosinophilia without evidence of end-organ manifestations or a primary myeloid etiology	—

PDGFR = platelet-derived growth factor receptor.

responsiveness to chemokines following activation also play important roles in eosinophil recruitment to the tissues and, ultimately, in disease pathogenesis.

Mutations

A number of recurrent genetic mutations have been described in clonal (neoplastic) eosinophilia.[5] The most common of these, an interstitial deletion in chromosome 4 leading to formation of the fusion gene *FIP1L1::PDGFRA*, likely causes eosinophil activation through a network of molecules including the IL-5 receptor, *JAK2*, and Lyn. The mechanisms of eosinophil activation in the setting of other mutations associated with clonal eosinophilia remain largely unexplored. Disease risk loci have been identified in a number of allergic disorders characterized by eosinophil accumulation and activation in tissues, including eosinophilic esophagitis.[6] Some of these, such as 5q22, encode genes known to be involved in eosinophil activation.

CLINICAL MANIFESTATIONS

The clinical manifestations of eosinophilia are very varied and include asymptomatic eosinophilia detected on a routine blood count, nonspecific symptoms such as fatigue and myalgia, and signs and symptoms related to eosinophilic tissue infiltration and/or complications of eosinophil-associated hypercoagulability. Although skin, pulmonary, and gastrointestinal manifestations are most frequent, any organ can be affected.[7] Moreover, there is considerable heterogeneity in the clinical manifestations within any given organ system. For instance, common presentations of eosinophilic skin involvement include intractable pruritus without rash, eczematous rash, urticaria, bullous lesions, and mucosal ulcerations. Although some clinical manifestations are more common in specific subtypes of hypereosinophilic syndrome (e.g., skin manifestations in lymphoid hypereosinophilic syndrome), there is considerable overlap in presentation among clinical subtypes. Moreover, the most serious clinical manifestations, such as endomyocardial fibrosis (Chapter 47)[8] and thromboembolism, can occur in any of the varied hypereosinophilic syndrome subtypes, including secondary or associated hypereosinophilic syndrome caused by untreated helminth infection or drug hypersensitivity.

DIAGNOSIS

Initial Diagnostic Evaluation

The first step in the diagnostic evaluation of the patient with eosinophilia is confirmation of the eosinophil count, while keeping in mind that fever, bacterial infection, and therapies, including glucocorticoids, that may be prescribed for other reasons can all suppress eosinophilia.[9] Once eosinophilia is confirmed, the next step is a search for secondary causes that require specific therapy directed at the underlying disorder (associated hypereosinophilic syndrome). If such a cause is identified, the patient should be treated and reassessed for resolution of the eosinophilia.

Differential Diagnosis

Patients with persistent eosinophilia and those without evidence of a clear secondary cause should undergo an initial evaluation aimed at the identification of end-organ involvement and classification by clinical subtype (Fig. 156-1). The

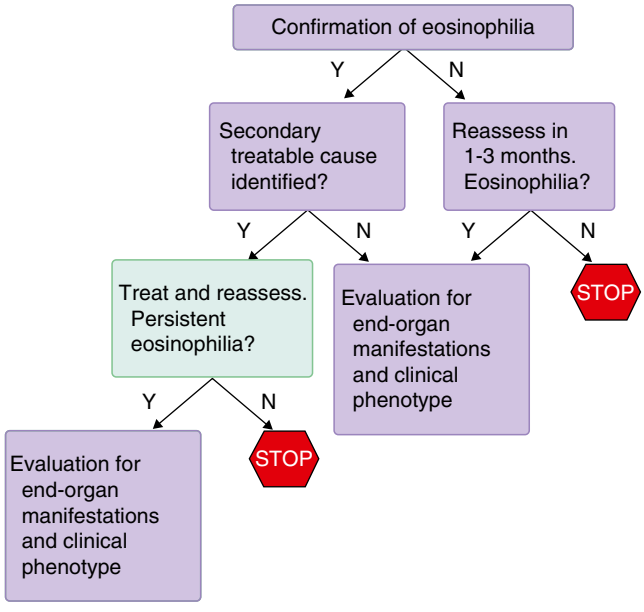

FIGURE 156-1. Initial approach to the clinically stable patient with unexplained eosinophilia. *Patients with idiopathic hypereosinophilia who are asymptomatic without end-organ manifestations are considered to have hypereosinophilia of undetermined significance (HEus).

diagnostic evaluation should be performed in a step-wise manner beginning with a careful history and physical examination, complete blood count with differential, and routine chemistries (including liver function tests and serum immunoglobulins). When possible, this evaluation should occur before institution of therapy because many diagnostic tests are affected by glucocorticoids and other therapies. However, treatment should not be delayed if life-threatening or disabling complications are present or imminent.

Although the differential diagnosis of eosinophilia is very broad, ranging from common allergic disorders to rare idiopathic hypereosinophilic syndromes, a careful history can substantially narrow the possibilities. Particular attention should be paid to medications and supplements, travel and exposures, risk factors for neoplasia, and prior medical history (especially asthma, atopic disease, and/or recurrent infections) because these may provide clues to secondary causes of eosinophilia, such as helminth infection, neoplasia, and immunodeficiency syndromes, that require therapy directed at the underlying cause rather than the eosinophilia itself (Table 156-2).[10] Whereas common allergic disorders, including asthma (Chapter 75) and atopic dermatitis (Chapter 405), can be associated with hypereosinophilia, especially in children, extremely high absolute eosinophil counts (≥5000/μL) should prompt evaluation for another cause. A detailed review of systems should

TABLE 156-2 SELECTED SECONDARY CAUSES OF EOSINOPHILIA REQUIRING TREATMENT DIRECTED AT THE UNDERLYING CAUSE

CATEGORY	ETIOLOGIES	COMMENTS
Infection		
Helminthic	Varied	Most pronounced early in infection and with tissue invasive species
Protozoan	*Isospora belli* infection *Sarcocystis* infection	Other protozoan infections are not associated with eosinophilia
Ectoparasitic	Scabies Myiasis	Hypersensitivity reactions
Viral	HIV infection	Advanced disease
Bacterial	Chronic tuberculosis	Rare
Fungal	Coccidioidomycosis Cryptococcosis	Eosinophilia can complicate a wide variety of fungal infections
Neoplasia	Lymphoma	Hodgkin, non-Hodgkin
	Leukemia	Especially T-cell leukemias and pre-B cell ALL
	Carcinoma	Most commonly adenocarcinoma
Drug hypersensitivity	Varied	Prescription and nonprescription drugs, dietary supplements
Immunodeficiency	Varied	Hyper-IgE syndromes Omenn syndrome
Autoimmune and other immunologic disorders	Varied	Sarcoidosis Inflammatory bowel disease IgG4 disease Others
Other	Cholesterol embolism Hypoadrenalism Radiation Post-transplant status Cytokine therapy: IL-2, GM-CSF	—

ALL = acute lymphoblastic leukemia; GM-CSF = granulocyte-macrophage colony-stimulating factor; HIV = human immunodeficiency virus; IgE = immunoglobulin E; IgG4 = immunoglobulin G4; IL-2 = interleukin-2.

be obtained in all patients because the pattern of clinical manifestations can be suggestive of a particular diagnosis. For example, a history of aspirin sensitivity in an eosinophilic patient with worsening asthma and sinusitis is highly suggestive of aspirin-exacerbated respiratory disease (Chapters 75 and 394),[11] whereas symptoms of peripheral neuropathy in a similar patient should point to a diagnosis of eosinophilic granulomatosis with polyangiitis (Chapter 249).

It is extremely important to identify patients with primary myeloid disorders presenting as hypereosinophilic syndrome because these patients often have aggressive disease, and the approach to therapy is quite different from that of other eosinophilic disorders (see the Treatment section). Clinical and laboratory features suggestive of a primary myeloid disorder include dysplastic eosinophils and eosinophil precursors in the blood, anemia or erythrocytosis, thrombocytopenia, splenomegaly, and elevated serum levels of vitamin B_{12} and/or tryptase. Male gender should raise suspicion for *PDGFR*-associated myeloid neoplasms in this setting.

An initial screen for evidence of myeloid or lymphocytic variant hypereosinophilic syndrome should include serum vitamin B_{12} and tryptase levels, as well as immunophenotyping for T- and B-cell clonality by flow cytometry. Abnormal results, a peripheral eosinophil count of 5000/μL or greater, or other evidence suggestive of a hematologic malignancy (including lymphadenopathy, splenomegaly, or dysplastic or precursor cells on peripheral blood smear) should prompt a bone marrow aspirate and biopsy with standard cytogenetic analysis. Specific testing for recurrent molecular abnormalities associated with hypereosinophilic syndrome should be guided by the clinical features and, if suspected, should be included with the bone marrow examination, where their yield may be higher than in peripheral blood.[12] Although the recommended testing for end-organ damage depends on the clinical signs and symptoms, serum troponin levels, echocardiography, and pulmonary function tests should be performed in all patients to assess clinically evident or occult cardiopulmonary involvement such as endomyocardial fibrosis that can be suggested by echocardiographic abnormalities. Radiologic imaging of the chest, abdomen, and pelvis should also be considered in all patients to identify splenomegaly, lymphadenopathy, and clinically silent neoplastic or inflammatory disease.

TREATMENT

Initial Therapy

The most appropriate initial treatment for a patient with eosinophilia depends on its most likely cause, acuity, and accompanying severity of the clinical signs and symptoms. Glucocorticoids remain the first-line agent for most hypereosinophilic disorders, with four important exceptions: hypereosinophilic syndrome secondary to a treatable cause (associated hypereosinophilic syndrome), primary clonal or neoplastic hypereosinophilic syndrome with an identified mutation for which targeted therapy is available (i.e., imatinib-sensitive, *PDGFR* mutation–positive hypereosinophilic syndrome), eosinophilic gastrointestinal disease (which can sometimes be treated with dietary intervention alone), and patients with hypereosinophilia of unknown significance (who may not require therapy at all). The most appropriate dose of glucocorticoids for an individual patient has not been adequately studied, but the clinical subtype appears to be a useful predictor of systemic glucocorticoid response in hypereosinophilic syndrome.[13] Some eosinophilic disorders, including eosinophilic esophagitis (Chapter 124) and eosinophilic dermatitis, can be successfully managed with topical steroid therapy alone. If life-threatening or disabling complications, such as endomyocardial fibrosis, respiratory failure, or neurologic impairment, are present or imminent, high-dose glucocorticoid therapy (40 mg of prednisone or more daily under expert oversight) should be initiated without delay, even in the setting of associated hypereosinophilic syndrome, unless a treatable secondary cause is identified and is likely to respond rapidly to specific therapy. Ivermectin (200 μg/kg/day for 1 to 2 days) should be administered prior to glucocorticoid therapy in patients with potential exposure to *Strongyloides stercoralis* at any time during their life to prevent hyperinfection syndrome. The most appropriate second agent for treatment of glucocorticoid-refractory patients depends on the clinical subtype and most likely etiology of the eosinophilia, as discussed later.

Initial treatment of myeloid neoplasms that present as a hypereosinophilic syndrome should be guided by the molecular findings. Imatinib (100 mg orally daily; Chapter 170) is clearly the therapy of choice in *PDGFR* mutation–associated disease, with near 100% response rates reported in most series and the possibility of cure in some patients with long-term therapy.[14] Results with other targeted therapies, including *JAK* inhibitors, have been variable in patients with myeloid forms of hypereosinophilic syndrome to date, even in the presence of mutations in the corresponding gene. Consequently, glucocorticoids are often used initially with rapid addition of hydroxyurea or other second-line agents as needed under expert oversight. This approach is likely to change, however, as more experience is gained with targeted therapies.

Second-Line Agents

The selection of a second-line agent depends on a variety of factors, including the clinical subtype, physician's and patient's preference, and cost. Conventional agents used to treat glucocorticoid-resistant, *PDGFR* mutation–negative patients include hydroxyurea, interferon-α, methotrexate, and imatinib. Patients who are *PDGFR* mutation positive and who are intolerant of or resistant to imatinib should be treated with a second- or third-generation tyrosine kinase inhibitor with activity against *PDGFR*, with early consideration of hematopoietic stem cell transplant in nonresponders.

Targeted Therapies

The availability of therapeutic agents that specifically target eosinophils is rapidly changing the approach to the treatment of eosinophilic disorders. Three biologics that target eosinophils through the IL-5 axis, mepolizumab, reslizumab, and benralizumab, have been approved for the treatment of eosinophilic asthma based on randomized trials documenting reduction in asthma exacerbations with little or no toxicity (Chapter 75).[A1,A2] Mepolizumab (300 mg subcutaneously every 4 weeks) improves remission rates and length of remission in patients with treatment-refractory or relapsing eosinophilic granulomatosis with polyangiitis[A3,A4] and reduces disease flares in patients with steroid-responsive *PDGFRA*-negative hypereosinophilic syndrome.[A5] In phase II trials, benralizumab (30 mg subcutaneously every 4 weeks) reduced eosinophilia and improved clinical manifestations in patients with treatment-refractory hypereosinophilic syndrome,[A6] and a phase III study is ongoing. Although dupilumab (a monoclonal antibody to the IL-4 receptor) is approved by the U.S. Food and Drug Administration for the treatment of a number of eosinophilic disorders, including atopic dermatitis, asthma, and eosinophilic esophagitis,[A7] it has been associated with transient hypereosinophilia and, rarely, eosinophilic complications, so it should be used with caution in patients with elevated eosinophil counts.[15] Other novel agents currently in development for eosinophilic disorders, including biologics targeting eotaxin, lirentelimab (a monoclonal antibody to Siglec 8) and dexpramipexole, are likely to provide additional therapeutic options for the heterogeneous group of eosinophilic disorders.

PROGNOSIS

Although the prognosis of an individual patient with hypereosinophilic syndrome depends substantially on the clinical subtype, the severity of clinical manifestations at presentation, and treatment responsiveness, the overall prognosis has improved dramatically (>90% 5-year survival in most series) with advances in diagnostic tools and therapeutic approaches. The most clear-cut example has been the dramatic decrease in mortality in patients with clinical features consistent with an eosinophilic myeloid neoplasm (the majority of whom have *FIP1L1::PDGFRA*–associated disease) with imatinib therapy. In fact, mortality and morbidity in this group of patients (which were 30 to 50% at 5 years before the introduction of imatinib) are now almost entirely restricted to patients who present with irreversible cardiac or other life-threatening manifestations. Progression to lymphoma remains a concern in patients with the lymphocytic variant, particularly in patients with CD3-CD4$^+$ T-cell clones.

157 APPROACH TO THE PATIENT WITH BLEEDING OR THROMBOSIS

ANDREW I. SCHAFER

MECHANISMS OF HEMOSTASIS AND THROMBOSIS

NORMAL HEMOSTASIS

The coagulation system is normally quiescent, and blood fluidity within blood vessels is maintained by the actions of a continuous monolayer of endothelial cells that line the intimal surface of the vasculature throughout the circulatory tree. At a site of vascular damage, the antithrombotic properties of endothelium are lost, and thrombogenic constituents of the subendothelial vessel wall become exposed to circulating blood. The result is rapid formation of a hemostatic clot that consists of platelets and fibrin and is localized to the area of vascular injury. Activation of platelets and formation of fibrin occur essentially simultaneously and interdependently to effect hemostasis. Subsequently, vascular repair is accomplished by thrombolysis and recanalization of the occluded site.[1]

Platelet activation at a site of vascular injury begins with the adhesion of platelets to the locally de-endothelialized intimal surface (i.e., platelet–vessel wall interaction). Platelet adhesion is mediated by von Willebrand factor, which sticks circulating platelets to the area of the damaged vessel wall by binding to its receptors located in platelet membrane glycoprotein Ib. The adherent platelets then undergo a "release reaction," during which they discharge constituents of their storage granules, including adenosine diphosphate (ADP), and simultaneously elaborate thromboxane A_2 from arachidonic acid through the aspirin-inhibitable cyclooxygenase reaction. ADP, thromboxane A_2, and other components of the release reaction act in concert to recruit and activate additional platelets from the circulation to the site of vascular injury. These activated platelets expose binding sites for fibrinogen by forming the surface membrane glycoprotein IIb/IIIa complex. In the process of platelet aggregation (platelet-platelet interactions), fibrinogen (or von Willebrand factor under conditions of high shear stress) mediates the final formation of an occlusive platelet plug.

Fibrin, which anchors the hemostatic platelet plug, is formed from soluble plasma fibrinogen by the action of the potent protease enzyme thrombin (Fig. 157-1). The fibrin mesh is stabilized by covalent cross-linking mediated by factor XIII. Thrombin is formed from its inactive (zymogen) plasma precursor, prothrombin, by the action of activated factor X (Xa) and its cofactor, factor Va. This sequence of reactions has classically been referred to as the *common pathway* of coagulation. Factor X can be activated by either the *tissue factor (extrinsic) pathway* or the *contact activation (intrinsic) pathway* of coagulation. The tissue factor pathway is now considered to be the major physiologic initiator of coagulation activation. It is triggered by the formation of the complex of tissue factor, which is exposed on the surfaces of activated vascular and blood cells, with activated factor VII (VIIa). The contact activation pathway involves a series (or cascade) of zymogen-protease reactions that are initiated by factor XII, high-molecular-weight kininogen, and prekallikrein. Activated factor XII (XIIa) converts factor XI to XIa, which in turn activates factor IX to IXa. Factor IXa is an enzyme that converts factor X to Xa, a reaction that requires factor VIIIa as a cofactor.

PHYSIOLOGIC ANTITHROMBOTIC MECHANISMS

Intact, normal endothelium promotes blood fluidity by inhibiting platelet activation. It likewise plays a crucial role in preventing fibrin accumulation.

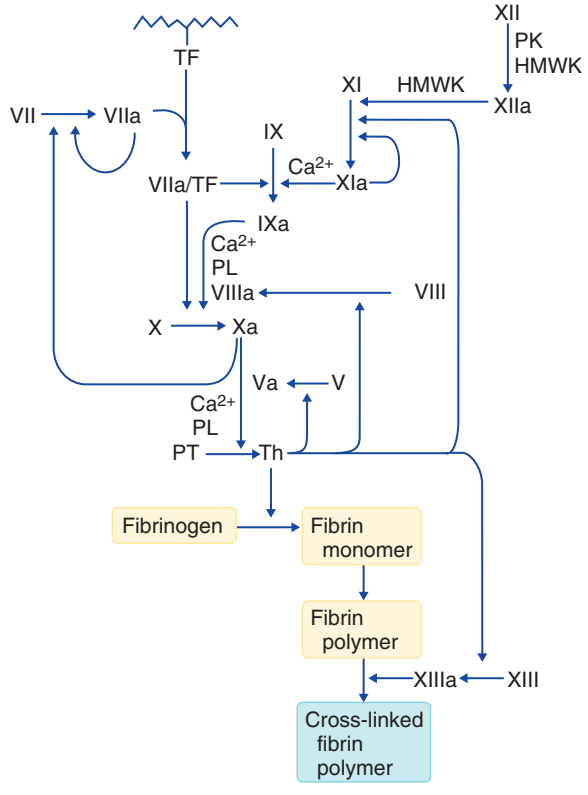

FIGURE 157-1. Coagulation cascade. This scheme emphasizes an understanding of (1) the importance of the tissue factor pathway in initiating clotting in vivo, (2) the interactions among pathways, and (3) the pivotal role of thrombin in sustaining the cascade by feedback activation of coagulation factors. HMWK = high-molecular-weight kininogen; PK = prekallikrein; PL = phospholipid; PT = prothrombin; TF = tissue factor; Th = thrombin. Roman numerals are coagulation factors (e.g., VII); when followed by a lowercase "a," they are the activated forms of those factors (e.g., VIIa). (From Schafer AI. Coagulation cascade: an overview. In: Loscalzo J, Schafer AI, eds. *Thrombosis and Hemorrhage*. Cambridge, MA: Blackwell Scientific Publications; 1994:3-12.)

157 APPROACH TO THE PATIENT WITH BLEEDING OR THROMBOSIS

ANDREW I. SCHAFER

MECHANISMS OF HEMOSTASIS AND THROMBOSIS

NORMAL HEMOSTASIS

The coagulation system is normally quiescent, and blood fluidity within blood vessels is maintained by the actions of a continuous monolayer of endothelial cells that line the intimal surface of the vasculature throughout the circulatory tree. At a site of vascular damage, the antithrombotic properties of endothelium are lost, and thrombogenic constituents of the subendothelial vessel wall become exposed to circulating blood. The result is rapid formation of a hemostatic clot that consists of platelets and fibrin and is localized to the area of vascular injury. Activation of platelets and formation of fibrin occur essentially simultaneously and interdependently to effect hemostasis. Subsequently, vascular repair is accomplished by thrombolysis and recanalization of the occluded site.[1]

Platelet activation at a site of vascular injury begins with the adhesion of platelets to the locally de-endothelialized intimal surface (i.e., platelet–vessel wall interaction). Platelet adhesion is mediated by von Willebrand factor, which sticks circulating platelets to the area of the damaged vessel wall by binding to its receptors located in platelet membrane glycoprotein Ib. The adherent platelets then undergo a "release reaction," during which they discharge constituents of their storage granules, including adenosine diphosphate (ADP), and simultaneously elaborate thromboxane A_2 from arachidonic acid through the aspirin-inhibitable cyclooxygenase reaction. ADP, thromboxane A_2, and other components of the release reaction act in concert to recruit and activate additional platelets from the circulation to the site of vascular injury. These activated platelets expose binding sites for fibrinogen by forming the surface membrane glycoprotein IIb/IIIa complex. In the process of platelet aggregation (platelet-platelet interactions), fibrinogen (or von Willebrand factor under conditions of high shear stress) mediates the final formation of an occlusive platelet plug.

Fibrin, which anchors the hemostatic platelet plug, is formed from soluble plasma fibrinogen by the action of the potent protease enzyme thrombin (Fig. 157-1). The fibrin mesh is stabilized by covalent cross-linking mediated by factor XIII. Thrombin is formed from its inactive (zymogen) plasma precursor, prothrombin, by the action of activated factor X (Xa) and its cofactor, factor Va. This sequence of reactions has classically been referred to as the *common pathway* of coagulation. Factor X can be activated by either the *tissue factor (extrinsic) pathway* or the *contact activation (intrinsic) pathway* of coagulation. The tissue factor pathway is now considered to be the major physiologic initiator of coagulation activation. It is triggered by the formation of the complex of tissue factor, which is exposed on the surfaces of activated vascular and blood cells, with activated factor VII (VIIa). The contact activation pathway involves a series (or cascade) of zymogen-protease reactions that are initiated by factor XII, high-molecular-weight kininogen, and prekallikrein. Activated factor XII (XIIa) converts factor XI to XIa, which in turn activates factor IX to IXa. Factor IXa is an enzyme that converts factor X to Xa, a reaction that requires factor VIIIa as a cofactor.

PHYSIOLOGIC ANTITHROMBOTIC MECHANISMS

Intact, normal endothelium promotes blood fluidity by inhibiting platelet activation. It likewise plays a crucial role in preventing fibrin accumulation.

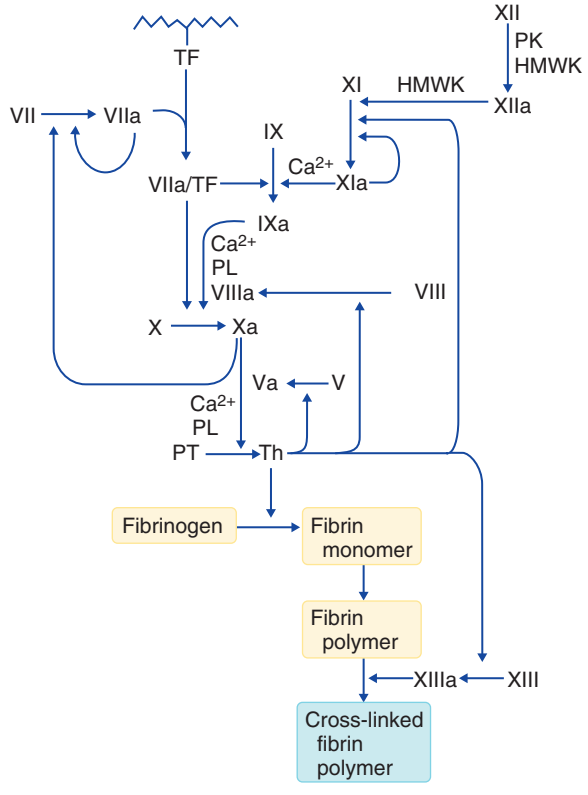

FIGURE 157-1. Coagulation cascade. This scheme emphasizes an understanding of (1) the importance of the tissue factor pathway in initiating clotting in vivo, (2) the interactions among pathways, and (3) the pivotal role of thrombin in sustaining the cascade by feedback activation of coagulation factors. HMWK = high-molecular-weight kininogen; PK = prekallikrein; PL = phospholipid; PT = prothrombin; TF = tissue factor; Th = thrombin. Roman numerals are coagulation factors (e.g., VII); when followed by a lowercase "a," they are the activated forms of those factors (e.g., VIIa). (From Schafer AI. Coagulation cascade: an overview. In: Loscalzo J, Schafer AI, eds. *Thrombosis and Hemorrhage*. Cambridge, MA: Blackwell Scientific Publications; 1994:3-12.)

ABSTRACT

Physiological coagulation in response to injury is referred to as *hemostasis*. Blood platelets and coagulation factors participate together in forming a hemostatic plug. Pathological coagulation, however, is referred to as *thrombosis*, which occurs when coagulation is abnormally hyperactive and is unneeded. Systemic bleeding disorders are caused by quantitative deficiencies or functional abnormalities in the coagulation cascade and in platelets. Thrombosis, particularly venous thrombosis, can be the result of deficiencies or functional abnormalities in physiological antithrombotic proteins (like antithrombin III, protein C, and protein S). Screening tests for systemic bleeding disorders (platelet count, prothrombin time [PT], and activated partial thromboplastin time [aPTT]) can rule out most, but not all, clinically significant coagulation abnormalities. For example, factor XIII deficiency or only mildly low coagulation factor levels will not be picked up by a prolonged PT or aPTT. Algorithms for more specialized tests are provided, and newer global coagulation and point-of-care tests are discussed. Evaluation of hypercoagulable states requires a panel of blood tests, since no well-validated screening tests are available.

inhibitors

Among the physiologic antithrombotic systems that produce this latter effect are (1) antithrombin III, (2) protein C and protein S, (3) tissue factor pathway inhibitor (TFPI), and (4) the fibrinolytic system. Antithrombin is the major protease inhibitor of the coagulation system: it inactivates thrombin and other activated coagulation factors. Heparin functions as an anticoagulant by binding to antithrombin and greatly accelerating these reactions. Heparin and heparin sulfate proteoglycans are naturally present on endothelial cells, so antithrombin inactivation of thrombin and other coagulation proteases most likely occurs physiologically on vascular surfaces rather than in fluid plasma. Activated protein C, with its cofactor protein S, functions as a natural anticoagulant by destroying factors Va and VIIIa, two essential cofactors of the coagulation cascade. Thrombin itself is the activator of protein C, and this reaction occurs rapidly only on the surfaces of intact vascular endothelial cells, where thrombin binds to the glycosaminoglycan thrombomodulin. TFPI is a plasma protease inhibitor that specifically quenches tissue factor–induced coagulation. Finally, what little fibrin can be produced, despite these potent physiologic antithrombotic mechanisms, is digested rapidly by the endogenous fibrinolytic system. Fibrinolysis is mediated by the protease plasmin, which is generated from plasminogen in plasma by the action of endothelium-derived plasminogen activators.

EVALUATION OF THE PATIENT WITH A POSSIBLE BLEEDING DISORDER

HISTORY AND PHYSICAL EXAMINATION

A thorough history is paramount in evaluating a patient for a possible systemic bleeding disorder. In addition to asking the patient about spontaneous bleeding episodes in the past, the responses to specific hemostatic challenges should be recorded. A bleeding tendency may be suspected if a patient previously experienced excessive hemorrhage after surgery or trauma, including common events such as circumcision, tonsillectomy, labor and delivery, menses, dental procedures, vaccinations, and injections. Conversely, a history of normal blood clotting after such specific challenges in the recent past is just as important to note. It may be a better test of the integrity of systemic hemostasis than any laboratory measurement can provide.

In a patient with a history of excessive or unexplained bleeding, the initial goal is to determine whether the cause is a systemic coagulopathy or localized anatomic or mechanical problem with a blood vessel. This situation is encountered most frequently in patients with excessive postoperative bleeding, which could be due to either local surgical trauma or a coagulation abnormality, or both. A history of prior bleeding suggests a coagulopathy, as does the finding of bleeding from multiple sites. However, this is not always the case. Even diffuse bleeding may arise from anatomic rather than hemostatic abnormalities, due to inherited or acquired primary vascular disorders rather than fluid-phase clotting abnormalities. Examples (Table 157-1) include Ehlers-Danlos syndrome; angiodysplasia; spontaneous, non-traumatic intracerebral hemorrhage caused by deep perforator arteriopathy or cerebral amyloid angiopathy; and recurrent mucosal hemorrhage in patients with hereditary hemorrhagic telangiectasia (Chapter 159). Conversely, a single episode of bleeding from an isolated site may be the initial manifestation of a systemic coagulopathy.

The history must include a survey of coexisting systemic diseases and drug ingestions that could affect hemostasis. Renal failure and the myeloproliferative neoplasms are associated with impaired platelet–vessel wall interactions and qualitative platelet abnormalities, connective tissue diseases and lymphomas are associated with thrombocytopenia, and liver disease causes a complex coagulopathy (Chapter 161). Ingestion of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) that cause nonselective inhibition of cyclooxygenase leads to platelet dysfunction; these drugs are often contained in over-the-counter preparations that patients may neglect to report without specific questioning. Other drugs, such as antibiotics, also may be associated with a bleeding tendency by causing abnormal platelet function or thrombocytopenia.[2] Finally, it is important to elicit a family history of bleeding problems. Although a positive history provides an important clue to a possible inherited coagulopathy, a negative history does not exclude a familial cause; for example, 20% of patients with classic hemophilia have a completely negative family history of bleeding.

Mild bleeding events are commonly reported by patients with and without subsequently laboratory-documented bleeding disorders, sometimes making it difficult for hematologists to define a "significant bleeding history." Using a web-based questionnaire, 25% of subjects in a healthy population reported epistaxis, 18% easy bruising (more commonly in women), 18% prolonged bleeding after dental extraction, and 47% of women heavy menstrual bleeding. Regarding the latter, in a study of 200 consecutive adolescents referred for heavy menstrual bleeding, a systemic bleeding disorder was diagnosed in 33%: low von Willebrand factor levels in 16%, von Willebrand disease in 11%, and qualitative platelet dysfunction in 4.5%.[3] More precise quantification of bleeding symptoms is being attempted by using "bleeding score" instruments such as the Vicenza bleeding score to help discriminate, in conjunction with laboratory testing, between healthy subjects and those with mild bleeding disorders.

Patterns of clinical bleeding, as revealed by the history and physical examination, may be characteristic of certain types of coagulopathy (Table 157-2). In general, patients with thrombocytopenia or qualitative platelet or vascular disorders present with bleeding from superficial sites in the skin and mucous membranes. These may involve petechiae, which are pinpoint cutaneous hemorrhages that appear particularly over dependent extremities (characteristic of severe thrombocytopenia), ecchymoses (common bruises), purpura, gastrointestinal and genitourinary tract bleeding, epistaxis, and hemoptysis. In these types of disorders, bleeding tends to occur spontaneously or immediately after trauma. In contrast, patients with inherited or acquired coagulation factor deficiencies, such as hemophilia, or those on anticoagulant therapy tend to bleed from deeper tissue sites (e.g., hemarthroses, deep hematomas, or retroperitoneal hemorrhage) and in a delayed manner after trauma.

LABORATORY TESTING

Screening Tests of Hemostasis

A few simple screening tests have traditionally been used in the initial evaluation of patients with a suspected coagulopathy: platelet count, bleeding time, prothrombin time (PT) (also reported as the INR), activated partial thromboplastin time (aPTT), and thrombin time (TT).[4] The North American Specialized Coagulation Laboratory Association (NASCOLA) has reported that most coagulation laboratories currently perform these tests as their "bleeding disorder panels."

Thrombocytopenia, reported by electronic particle counting, should be verified by examination of the peripheral smear. Pseudothrombocytopenia, a laboratory artifact of ex vivo platelet clumping, may be caused by the ethylenediaminetetraacetic acid (EDTA) anticoagulant used in tubes for blood cell counts, by other anticoagulants, or by nonphysiologic cold agglutinins acting at room temperature. It should be suspected whenever a very low platelet count is unexpectedly reported in a patient who does not exhibit any clinical

TABLE 157-1 CHARACTERISTIC PATTERNS OF BLEEDING IN SYSTEMIC DISORDERS OF HEMOSTASIS

TYPE OF DISORDER	*SITES OF BLEEDING*				ONSET OF BLEEDING	CLINICAL EXAMPLES
	GENERAL	SKIN	MUCOUS MEMBRANES	OTHER		
Platelet-vascular disorders	Superficial surfaces	Petechiae, ecchymoses	Common: oral, nasal, gastrointestinal, genitourinary	Rare	Spontaneous or immediately after trauma	Thrombocytopenia, functional platelet disorder, vascular fragility, disseminated intravascular coagulation, liver disease
Coagulation factor deficiency	Deep tissues	Hematomas	Rare	Common: joint, muscle, retroperitoneal	Delayed after trauma	Inherited coagulation factor deficiency, acquired inhibitor, anticoagulation, disseminated intravascular coagulation, liver disease

TABLE 157-2 FEATURES OF COAGULATION FACTOR DEFICIENCIES

DEFICIENCY	TYPICAL LABORATORY FINDINGS	APPROXIMATE PREVALENCE
Fibrinogen	Afibrinogenemia: TT ↑↑, aPTT ↑↑, PT ↑↑ Dysfibrinogenemia and hypofibrinogenemia: TT ↑, aPTT ↑, PT ↑↑	1 in 1 million
Prothrombin	TT normal, aPTT ↑, PT ↑	1 in 2 million
Factor V	TT normal, aPTT ↑, PT ↑	1 in 1 million
Combined factor V and VIII	TT normal, aPTT ↑, PT ↑	1 in 1 million
Factor VII	TT normal, aPTT normal, PT ↑	1 in 500,000
Factor X	TT normal, aPTT ↑, PT ↑	1 in 1 million
Factor XI	TT normal, aPTT ↑, PT normal	1 in 1 million
Factor XIII	TT, aPTT, and PT normal; specific assays required	1 in 2 million
Vitamin K–dependent coagulation factors	TT normal, aPTT ↑, PT ↑↑	<50 families reported

aPTT = activated partial thromboplastin time; PT = prothrombin time; TT = thrombin time.

bleeding. Pseudothrombocytopenia is indicated by the finding of platelet clumps on the peripheral smear, and the diagnosis is supported by the finding of simultaneously normal platelet counts in blood samples obtained by finger stick, in tubes containing other anticoagulants, or in a tube maintained at 37° C before platelet counting. Examination of the blood smear can also reveal clues to the cause of real thrombocytopenia, such as fragmented red blood cells in thrombotic thrombocytopenic purpura.

The bleeding time was a widely used clinical screening test for disorders of platelet–vessel wall interactions. It measures the time to cessation of bleeding after a standardized incision over the volar aspect of the forearm. However, the test is prone to problems related to quality control, reproducibility, sensitivity, and specificity. Therefore, because von Willebrand disease is the most common genetic cause of abnormal platelet–vessel wall interactions, most experts now recommend replacing the bleeding time with specific tests for von Willebrand disease (vWd screen) in the initial evaluation of patients with a suspected coagulopathy (Chapter 159). The entity of "low von Willebrand factor" activity (≥30 and ≤50 IU/dL), not meeting the diagnostic criteria of von Willebrand disease, has been associated with a bleeding tendency.[5] As an additional replacement for the bleeding time, especially when a functional (qualitative) abnormality of platelets is suspected by characteristic mucocutaneous bleeding or bruising, a global assay of platelet function can be appended to the panel of screening tests. This is most commonly a platelet function analyzer (PFA) closure time. The PFA and other platelet function studies (see later) must be performed after discontinuation of drugs that interfere with platelet function (e.g., aspirin and other NSAIDs).

The PT measures the integrity of the extrinsic and common pathways of coagulation (factors VII, X, and V; prothrombin; and fibrinogen) (Fig. 157-2). The aPTT measures the integrity of the intrinsic and common pathways of coagulation (high-molecular-weight kininogen; prekallikrein; factors XII, XI, IX, VIII, X, and V; prothrombin; and fibrinogen). The sensitivity of the PT and aPTT in detecting coagulation factor deficiencies may vary with the reagents used to perform these tests, and each laboratory must determine its own reference standards. It is important to note that the PT and aPTT are generally not sensitive enough to detect mild coagulation factor deficiencies, where the deficient factor level is >25%. For example, an individual with mild hemophilia (with factor VIII level of 35%) is likely to have a normal aPTT.[6] The TT is a screen for quantitative deficiencies and qualitative defects of plasma fibrinogen.

Follow-Up of Abnormal Screening Tests

Abnormalities in these screening tests of hemostasis may be pursued by more specialized tests to establish a specific diagnosis (Fig. 157-3).

An abnormal von Willebrand disease screen should be followed up with more specialized tests, including von Willebrand factor multimer analysis, to identify the type of von Willebrand disease involved. Abnormalities in the PFA closure time should be followed by more specialized light transmission aggregometry (LTA) of platelets using a panel of agonists (ADP, epinephrine, collagen, arachidonic acid, ristocetin) that induce characteristic changes in light transmission (or optical density) in stirred suspensions of freshly isolated platelets in plasma (PRP). LTA is still considered the "gold standard" for platelet function testing[7] (Chapter 159). In patients who have clinical bleeding problems, inherited disorders of platelet function are increasingly diagnosed by genomic testing.[8]

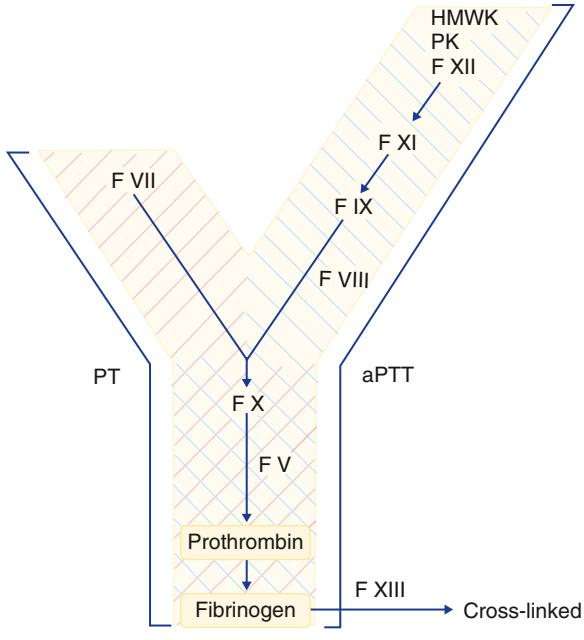

FIGURE 157-2. Classic coagulation cascade. The prothrombin time (PT) measures the integrity of the extrinsic and common pathways, whereas the activated partial thromboplastin time (aPTT) measures the integrity of the intrinsic and common pathways. Factor (F) XIII deficiency is not detected by PT or aPTT. HMWK = high-molecular-weight kininogen; PK = prekallikrein.

The finding of a prolonged PT and/or aPTT indicates either a deficiency of one or more coagulation factors or the presence of an inhibitor (Fig. 157-4), usually an antibody, directed at one or more components of the coagulation system. These two possibilities can be distinguished by performing a simple inhibitor screen, which involves a 1:1 mix of the patient's plasma and normal plasma. The premise of the test is that even if the patient's plasma is completely deficient (0% level) in a certain factor, mixing it 1:1 with normal plasma (100% level) should bring the concentration of that factor to 50% in the mixture; this is sufficient to correct the prolonged PT or aPTT. If correction occurs with the inhibitor screen, individual coagulation factor levels should be assayed for a specific deficiency state. If the 1:1 mix fails to correct the prolonged PT and/or aPTT, an inhibitor is likely to be present, and it is interfering with coagulation in vitro in both the patient's plasma and the normal plasma. Specific assays should then be performed to determine whether there is a true inhibitor against a coagulation factor (e.g., factor VIII antibody) or whether the inhibitor is a lupus anticoagulant. A prolonged TT, with or without prolongation of the PT and/or aPTT, suggests the presence of a quantitative deficiency or a qualitative defect of fibrinogen. These can then be distinguished by following up with simultaneously performed clottable (functional) and antigenic assays of fibrinogen: a disproportionately low clottable fibrinogen points to a functional fibrinogen abnormality (dysfibrinogenemia), whereas

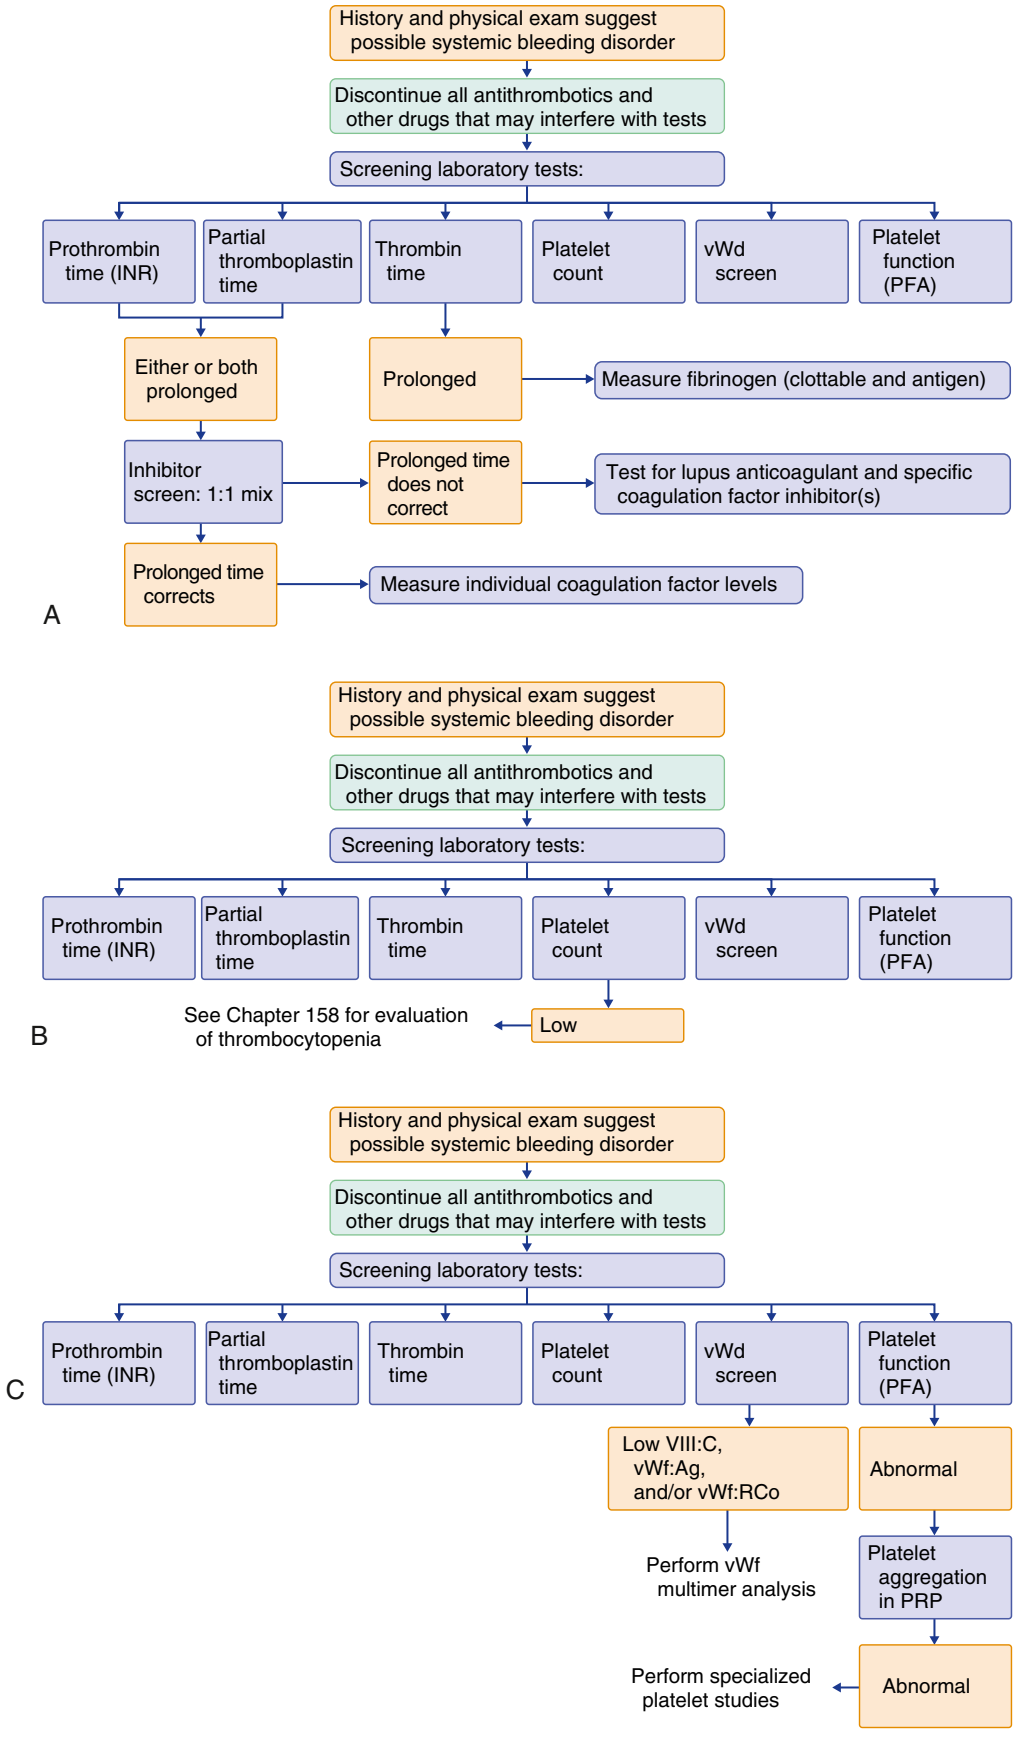

FIGURE 157-3. **Algorithms for clinical and laboratory approach to the diagnosis of a patient with a suspected systemic bleeding disorder (coagulopathy). A to C,** The critical importance of a thorough personal and family history and physical examination is emphasized before initiating a laboratory work-up. INR = international normalized ratio; PFA = platelet function analyzer; PRP = platelet-rich plasma; VIII:C = factor VIII coagulant activity; vWD = von Willebrand disease; vWf = von Willebrand factor; vWf:Ag = von Willebrand factor antigen; vWf:RCo = von Willebrand factor: ristocetin cofactor activity.

proportionately reduced levels of clottable and antigenic fibrinogen suggest a quantitative deficiency (hypofibrinogenemia or afibrinogenemia) (see Fig. 157-3A and Chapter 160).

Suspected Coagulopathy Despite Negative Screening Tests

Normal results for all these screening tests of hemostasis essentially usually exclude any clinically significant systemic coagulopathy. When all screening tests of coagulation are normal in a patient who is strongly suspected of having a systemic bleeding disorder, further testing might be necessary. Individual coagulation factor assays can reveal a mild factor deficiency even when the PT and aPTT are normal. Activated factor XIII catalyzes the covalent cross-linking of polymerized fibrin to solidify clot formation in vivo. However, the PT, aPTT, and thrombin time tests in vitro detect the formation of only fibrin that is not yet cross-linked (see Fig. 157-2). Therefore, since factor XIII deficiency (Chapter 160) is not detected by the PT and aPTT, specific testing for factor XIII activity is required.

Rare disorders of fibrinolysis also may be associated with normal screening tests, thereby necessitating more specialized tests when indicated (Chapter 161). Bleeding due to hyperfibrinolysis can be caused by increased levels of the fibrinolytic enzyme, plasmin. In turn, increased plasmin generation can be due to increased activators (tissue-plasminogen activator [tPA]), decreased plasmin substrate (hypoplasminogenemia), or decreased fibrinolytic inhibitors (α2-antiplasmin, plasminogen activator inhibitor-1 [PAI-1], or thrombin activatable fibrinolysis inhibitor [TAFI]). All of these proteins, as well as quantitative D-dimer levels, can be measured in clinical laboratories.[9]

Newer coagulation tests, known as global assays, have the potential to offer a more complete evaluation of a patient's overall clot-forming capability. These global assays, including thrombin generation tests and viscoelastic assays, have not yet advanced from experimental research to routine clinical practice.

Global Coagulation Laboratory and Point-of-Care Tests

Thrombin Generation Tests

Thrombin generation tests require separation of platelet-poor plasma (PPP) or platelet-rich plasma (PRP) from centrifuged whole blood. Thrombin generation in the patient's plasma can be then measured by comparing it to a calibrator of known thrombin activity, using automated fluorescence or chromogenic readouts. These tests measure primarily the coagulation arm of hemostasis and have been shown to be promising in evaluating thrombophilias in guiding antithrombotic therapy. The tests are limited at this time by their lack of validation as a clinical tool.

Clot Waveform Analysis

This test is based on the activated partial thromboplastin time (aPTT) assay, but with a prolonged light transmission readout that can monitor both the acceleration and deceleration of clotting, thereby reflecting the whole process of clot formation and clot lysis. It shows promise as a global test of disseminated intravascular coagulation (DIC) and for sensitive detection of mild coagulation factor deficiencies, but the method needs further validation and standardization.

Thromboelastography

Two types of semiautomated commercial devices available provide global assays of coagulation and fibrinolysis using point-of-care technology: the ROTEM (rotational thromboelastometry) analyzer and the thromboelastography analyzers. These tests are whole blood clotting tests in which a small aliquot of blood is rotated in a cuvette, and the strength, elasticity, and dissolution of the forming clot are measured with a torsion wire or by optical detection. The markedly increasing use of this technology is understandable; it is inherently attractive to have a bedside test that provides immediate, real-time, visualized monitoring and analysis of clot formation and lysis in whole blood incorporating the totality of the hemostatic system, including coagulation, fibrinolysis, and platelets.[10] A randomized trial of thromboelastography-guided blood component use in patients with cirrhosis and nonvariceal bleeding found that it leads to a significantly lower use of blood components than transfusions guided by INR and platelet count.[A1] However, systematic reviews have concluded at this time that most meaningful data on thromboelastography have come from their use in cardiac surgery involving cardiopulmonary bypass, where it has indeed reduced the need for transfusion of blood products.[A2] Randomized clinical trials have found that the use of thromboelastography-guided algorithms in place of traditional transfusion parameters in cirrhotic patients with severe coagulopathy (i.e., platelets <50,000 and/or INR >1.8) who are having active bleeding reduces the number of platelet, plasma, and cryoprecipitate transfusions.[A3] Its impact on producing other favorable clinical end points remains open to study.[11] For example, in two randomized trials, adding viscoelastography to routine coagulation studies did not improve overall outcomes after major trauma,[A4] and adding thromboelastography to such studies led to only a small reduction in blood loss from postpartum hemorrhage.[A5]

Other Point-of-Care Tests of Hemostasis

Other, more specialized but established point-of-care tests of hemostasis include the activated clotting time (ACT), which is used to monitor heparinization during extracorporeal circuits in cardiac bypass surgery and extracorporeal membrane oxygenation; handheld devices to measure the international normalized ratio (INR) for self-management at-home monitoring in patients taking vitamin K antagonists; and platelet function analyzers (i.e., the VerifyNow system), which measure platelet aggregation across fibrinogen-coated polystyrene beads in separate cartridges for assessment of resistance to antiplatelet drugs including aspirin, thienopyridines, and glycoprotein IIb-IIIa antagonists.

High-Throughput Sequencing

High-throughput sequencing can detect a molecular diagnosis in about 50% of all patients with a thrombotic, coagulation, platelet count, or platelet function disorder. In patients with otherwise unexplained bleeding disorders and normal hemostatic test results, it can find a molecular diagnosis in about 3% of patients.[12]

EVALUATION OF THE ASYMPTOMATIC PATIENT WITH ABNORMAL COAGULATION TESTS

In asymptomatic individuals who are discovered incidentally to have abnormalities in screening laboratory tests of hemostasis, the first critical question to ask is whether the findings are clinically relevant. Patients with inherited deficiencies of one of the contact activation coagulation factors (factor XII, high-molecular-weight kininogen, prekallikrein) characteristically have a markedly prolonged aPTT, yet they do not have a clinical bleeding tendency. Likewise, patients with lupus anticoagulants typically have prolongation of the aPTT and sometimes also the PT; they much more often have thrombotic rather than bleeding complications. In patients with heparin-induced thrombocytopenia, a marked decrease in the platelet count is sometimes associated with arterial and venous thrombosis rather than bleeding. It is crucial to view the clinical setting, history, physical examination, and screening laboratory tests as complementary facets of the approach to patients with suspected coagulopathies.

EVALUATION OF THE PREOPERATIVE PATIENT

Routine screening of all preoperative patients with a platelet count, bleeding time, PT, and aPTT is not only uninformative but also may be counterproductive if follow-up testing causes unnecessary expense and delays in surgery (Chapter 399). Preoperative bleeding time, PT, and aPTT do not predict surgical bleeding risk in patients who are not found to be at increased risk on clinical grounds, so a thorough clinical assessment should guide the need for these preoperative screening tests. Laboratory testing and possibly further specialized tests of coagulation are indicated for patients whose bleeding histories

are suspicious for a hemostatic abnormality. Preoperative screening tests of coagulation are probably warranted for patients who cannot cooperate with an adequate clinical assessment and for those who will be undergoing procedures in which even minimal postoperative hemorrhage could be hazardous. Recent guidelines for preinterventional and preoperative hemostatic evaluation have likewise concluded that bleeding risk requires a detailed personal and family history of hemorrhagic events and physical examination; but individuals with a negative history and without conditions that may interfere with systemic hemostasis should not undergo coagulation testing.[13]

EVALUATION OF THE PATIENT WITH A POSSIBLE HYPERCOAGULABLE STATE

Most patients with venous thromboembolism (VTE) have an inherited basis for hypercoagulability (Chapter 67). Patients with inherited hypercoagulable states (or thrombophilia) typically present with an initial episode of VTE in early adulthood, but thrombotic manifestations may begin at any time from early childhood to old age. Patients usually have deep vein thrombosis of the lower extremities or pulmonary embolism, but other uncommon sites of venous thrombosis may be involved. Arterial thrombosis is not characteristically associated with inherited hypercoagulable states. Arterial thrombosis that occurs prematurely or in the absence of apparent risk factors should trigger a different line of investigation, possibly including evaluation for vasculitis, myeloproliferative neoplasms, hyperhomocysteinemia, antiphospholipid syndrome, and potential sources of systemic embolization.

The primary or hereditary hypercoagulable states (see Table 67-1) result from specific mutations or polymorphisms that lead to decreased levels of physiologic antithrombotic proteins or increased levels of procoagulant proteins. In contrast, the secondary or acquired hypercoagulable states are a heterogeneous group of disorders that predispose to thrombosis by complex mechanisms. VTE is often provoked by the combination of an underlying hypercoagulable genotype and an acquired prothrombotic, hypercoagulable state such as pregnancy, immobilization, or the postoperative state. Certain clinical characteristics suggest the presence of an inherited hypercoagulable state (Table 157-3). Patients with recurrent thrombosis should be tested for these disorders and, in most cases, committed to lifelong prophylactic anticoagulation. It is not clear whether it is essential to order these tests after a single episode of VTE. Counterintuitively, it has been found that most of the common inherited hypercoagulable states—which, to varying extents, clearly increase the risk for a *first* episode of VTE—are at best only weak predictors of *recurrent* VTE. It has been argued, therefore, that making a specific thrombophilia diagnosis after an initial episode of VTE will not influence the decision about the duration of prophylactic anticoagulation.[14] However, the increased risk for recurrent VTE with the more strongly prothrombotic mutations (e.g., antithrombin III, protein C or S deficiency), combined inherited thrombophilias, or antiphospholipid syndrome may necessitate long-term anticoagulation, and therefore their diagnosis after a first episode of VTE would in fact alter decisions about the duration of anticoagulation (see Fig. 67-1). Even if they are not maintained on long-term anticoagulation, patients with diagnosed primary hypercoagulable states should receive prophylactic anticoagulation during situations that pose a high risk for thrombosis, such as the peripartum period. There is no simple screening test for primary hypercoagulable states, and the timing of obtaining these tests is crucial to avoid erroneous diagnoses.[15] Acute thrombosis itself can cause transient decreases in the levels of antithrombin, protein C, and protein S. Heparin therapy can cause a decrease in plasma antithrombin activity. Warfarin therapy lowers the functional levels of protein C and protein S. Inherited deficiency states can be diagnosed spuriously under these conditions. Use of one of the newer anticoagulants can also interfere with laboratory tests, especially for lupus anticoagulant.

Patients who present with VTE have an increased risk for harboring an occult malignancy. This association is increased further in patients with recurrent and unprovoked thrombosis. There are conflicting opinions on whether an evaluation for occult malignancy in these patients must be exhaustive. Most recommend that evaluation can be limited to a thorough history, physical examination, routine complete blood cell count and chemistries, test of fecal occult blood, urinalysis, mammogram (in women), and chest radiograph, with further testing guided by any abnormalities found in this initial evaluation. Routine computed tomography scanning of the chest, abdomen, and pelvis is not indicated[A6] unless other testing suggests an abnormality[16] (see algorithm in Fig. 67-3).

In addition to classic deep vein thrombosis and pulmonary embolism, certain characteristic types of thrombosis may provide important clues to the cause and trigger a more directed evaluation. Migratory, superficial thrombophlebitis (Trousseau syndrome) or nonbacterial thrombotic endocarditis strongly suggests the presence of an occult malignancy (Chapter 67). Hepatic vein thrombosis (Budd-Chiari syndrome; Chapter 129) or portal vein thrombosis may indicate a myeloproliferative neoplasm (Chapter 152) or paroxysmal nocturnal hemoglobinuria (Chapter 146). Extensive inferior vena cava thrombosis may occur with renal cell carcinoma (Chapter 182). Warfarin-induced skin necrosis strongly suggests underlying protein C or protein S deficiency. Recurrent, spontaneous miscarriages are characteristic of the antiphospholipid syndrome (Chapter 160), although they are also associated with other thrombophilias.

TABLE 157-3 CLINICAL CHARACTERISTICS OF PATIENTS WITH INHERITED HYPERCOAGULABLE STATES (THROMBOPHILIA)

Venous thromboembolism (>90% of cases)
Deep vein thrombosis or pulmonary embolism most common
Splanchnic or cerebral vein thrombosis rare but characteristic
Frequent family history of thrombosis
Typically autosomal dominant
First episode of thrombosis typically in young adulthood (<40 years)
Often apparently unprovoked (but an acquired thrombosis trigger is frequently identified with a careful history)
More common thrombophilias (factor V Leiden, prothrombin 20210 G→A) are associated with a lower thrombosis risk; rarer thrombophilias (antithrombin III, protein C, protein S deficiency) are associated with a higher thrombosis risk
Warfarin-induced skin necrosis or neonatal purpura fulminans with protein C or protein S deficiency (very rare)

158 THROMBOCYTOPENIA

CHARLES S. ABRAMS

DEFINITION

Thrombocytopenia is defined as a platelet count lower than the normal range, typically below 140,000/μL.

EPIDEMIOLOGY

With the widespread use of the routine complete blood count (CBC), asymptomatic individuals with incidentally discovered mild thrombocytopenia are being increasingly recognized. The clinical significance of mild thrombocytopenia (platelet counts between 100,000/μL and 150,000/μL) in the absence of

are suspicious for a hemostatic abnormality. Preoperative screening tests of coagulation are probably warranted for patients who cannot cooperate with an adequate clinical assessment and for those who will be undergoing procedures in which even minimal postoperative hemorrhage could be hazardous. Recent guidelines for preinterventional and preoperative hemostatic evaluation have likewise concluded that bleeding risk requires a detailed personal and family history of hemorrhagic events and physical examination; but individuals with a negative history and without conditions that may interfere with systemic hemostasis should not undergo coagulation testing.[13]

EVALUATION OF THE PATIENT WITH A POSSIBLE HYPERCOAGULABLE STATE

Most patients with venous thromboembolism (VTE) have an inherited basis for hypercoagulability (Chapter 67). Patients with inherited hypercoagulable states (or thrombophilia) typically present with an initial episode of VTE in early adulthood, but thrombotic manifestations may begin at any time from early childhood to old age. Patients usually have deep vein thrombosis of the lower extremities or pulmonary embolism, but other uncommon sites of venous thrombosis may be involved. Arterial thrombosis is not characteristically associated with inherited hypercoagulable states. Arterial thrombosis that occurs prematurely or in the absence of apparent risk factors should trigger a different line of investigation, possibly including evaluation for vasculitis, myeloproliferative neoplasms, hyperhomocysteinemia, antiphospholipid syndrome, and potential sources of systemic embolization.

The primary or hereditary hypercoagulable states (see Table 67-1) result from specific mutations or polymorphisms that lead to decreased levels of physiologic antithrombotic proteins or increased levels of procoagulant proteins. In contrast, the secondary or acquired hypercoagulable states are a heterogeneous group of disorders that predispose to thrombosis by complex mechanisms. VTE is often provoked by the combination of an underlying hypercoagulable genotype and an acquired prothrombotic, hypercoagulable state such as pregnancy, immobilization, or the postoperative state. Certain clinical characteristics suggest the presence of an inherited hypercoagulable state (Table 157-3). Patients with recurrent thrombosis should be tested for these disorders and, in most cases, committed to lifelong prophylactic anticoagulation. It is not clear whether it is essential to order these tests after a single episode of VTE. Counterintuitively, it has been found that most of the common inherited hypercoagulable states—which, to varying extents, clearly increase the risk for a *first* episode of VTE—are at best only weak predictors of *recurrent* VTE. It has been argued, therefore, that making a specific thrombophilia diagnosis after an initial episode of VTE will not influence the decision about the duration of prophylactic anticoagulation.[14] However, the increased risk for recurrent VTE with the more strongly prothrombotic mutations (e.g., antithrombin III, protein C or S deficiency), combined inherited thrombophilias, or antiphospholipid syndrome may necessitate long-term anticoagulation, and therefore their diagnosis after a first episode of VTE would in fact alter decisions about the duration of anticoagulation (see Fig. 67-1). Even if they are not maintained on long-term anticoagulation, patients with diagnosed primary hypercoagulable states should receive prophylactic anticoagulation during situations that pose a high risk for thrombosis, such as the peripartum period. There is no simple screening test for primary hypercoagulable states, and the timing of obtaining these tests is crucial to avoid erroneous diagnoses.[15] Acute thrombosis itself can cause transient decreases in the levels of antithrombin, protein C, and protein S. Heparin therapy can cause a decrease in plasma antithrombin activity. Warfarin therapy lowers the functional levels of protein C and protein S. Inherited deficiency states can be diagnosed spuriously under these conditions. Use of one of the newer anticoagulants can also interfere with laboratory tests, especially for lupus anticoagulant.

Patients who present with VTE have an increased risk for harboring an occult malignancy. This association is increased further in patients with recurrent and unprovoked thrombosis. There are conflicting opinions on whether an evaluation for occult malignancy in these patients must be exhaustive. Most recommend that evaluation can be limited to a thorough history, physical examination, routine complete blood cell count and chemistries, test of fecal occult blood, urinalysis, mammogram (in women), and chest radiograph, with further testing guided by any abnormalities found in this initial evaluation. Routine computed tomography scanning of the chest, abdomen, and pelvis is not indicated[A6] unless other testing suggests an abnormality[16] (see algorithm in Fig. 67-3).

In addition to classic deep vein thrombosis and pulmonary embolism, certain characteristic types of thrombosis may provide important clues to the cause and trigger a more directed evaluation. Migratory, superficial thrombophlebitis (Trousseau syndrome) or nonbacterial thrombotic endocarditis strongly suggests the presence of an occult malignancy (Chapter 67). Hepatic vein thrombosis (Budd-Chiari syndrome; Chapter 129) or portal vein thrombosis may indicate a myeloproliferative neoplasm (Chapter 152) or paroxysmal nocturnal hemoglobinuria (Chapter 146). Extensive inferior vena cava thrombosis may occur with renal cell carcinoma (Chapter 182). Warfarin-induced skin necrosis strongly suggests underlying protein C or protein S deficiency. Recurrent, spontaneous miscarriages are characteristic of the antiphospholipid syndrome (Chapter 160), although they are also associated with other thrombophilias.

TABLE 157-3 CLINICAL CHARACTERISTICS OF PATIENTS WITH INHERITED HYPERCOAGULABLE STATES (THROMBOPHILIA)

Venous thromboembolism (>90% of cases)
Deep vein thrombosis or pulmonary embolism most common
Splanchnic or cerebral vein thrombosis rare but characteristic
Frequent family history of thrombosis
Typically autosomal dominant
First episode of thrombosis typically in young adulthood (<40 years)
Often apparently unprovoked (but an acquired thrombosis trigger is frequently identified with a careful history)
More common thrombophilias (factor V Leiden, prothrombin 20210 G→A) are associated with a lower thrombosis risk; rarer thrombophilias (antithrombin III, protein C, protein S deficiency) are associated with a higher thrombosis risk
Warfarin-induced skin necrosis or neonatal purpura fulminans with protein C or protein S deficiency (very rare)

158 THROMBOCYTOPENIA

CHARLES S. ABRAMS

DEFINITION

Thrombocytopenia is defined as a platelet count lower than the normal range, typically below 140,000/μL.

EPIDEMIOLOGY

With the widespread use of the routine complete blood count (CBC), asymptomatic individuals with incidentally discovered mild thrombocytopenia are being increasingly recognized. The clinical significance of mild thrombocytopenia (platelet counts between 100,000/μL and 150,000/μL) in the absence of

ABSTRACT

Thrombocytopenia can be caused by three general mechanisms: increased destruction of circulating platelets; impaired production of platelets by the bone marrow; or increased splenic sequestration of circulating platelets. Splenic sequestration is a passive rather than actively destructive process caused by expansion of the splenic platelet pool and splenic enlargement of congestive (e.g., portal hypertension) or infiltrative (e.g., lymphoma or storage disease) etiologies. Destructive thrombocytopenias can be immune- or nonimmune-mediated. The former includes immune thrombocytopenia purpura (ITP) and drug-induced thrombocytopenia; the latter can be caused by TTP, HUS, DIC, and intravascular devices. Before initiating an extensive workup for the cause of the thrombocytopenia, the peripheral blood smear should be examined for artifactual platelet clumping ("pseudothrombocytopenia"), an idiosyncratic in vitro phenomenon that should be especially suspected in a patient reported to have an unexpectedly low platelet count in the absence of any clinical bleeding. Mild thrombocytopenia can be congenital or occur physiologically with the progression of a normal pregnancy (gestational thrombocytopenia).

KEYWORDS

thrombotic thrombocytopenic purpura (TTP)
hemolytic-uremic syndrome (HUS)
disseminated intravascular coagulation (DIC)
pseudothrombocytopenia

other CBC abnormalities can be difficult to ascertain. Many, and perhaps most, of these individuals with mild chronic thrombocytopenia represent outliers of the normal distribution of platelet counts. However, others have thrombocytopenia that represents the early manifestation of an unrecognized disease.

After a decade, approximately 10% of patients with mild immune thrombocytopenia will develop ITP or another autoimmune disorder. However, approximately 90% of the subjects will continue to manifest borderline thrombocytopenia without developing another disorder during this period of time. It can be concluded that most individuals with isolated and asymptomatic chronic mild thrombocytopenia simply represent the lower end of the normal platelet count distribution. Consequently, international consensus groups have set the threshold for the diagnosis of ITP at a platelet count of less than 100,000/μL.

PATHOBIOLOGY

The causes of thrombocytopenia can be divided into three major categories: increased destruction of platelets, such as seen in immune-mediated causes; decreased production of platelets, usually due to an underlying bone marrow disorder; or sequestration of platelets within the spleen, as occurs in conditions that cause splenomegaly (hypersplenism).

Increased Platelet Destruction

In the absence of splenomegaly, the presence of increased megakaryocytes in an otherwise normal bone marrow implies that thrombocytopenia is due to increased platelet destruction. An acute drop in a patient's platelet count also implies that a peripheral destructive process is the likely cause. For example, a patient who develops abrupt thrombocytopenia during hospitalization most likely has a low platelet count caused by an infection or by the introduction of a new medication. Both nonimmune and immune processes can lead to a shortened platelet lifespan. Nonimmune reasons for the accelerated destruction of platelets include sepsis, disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), preeclampsia or eclampsia, cardiopulmonary bypass, and giant cavernous hemangioma. Thrombocytopenia that occurs in these circumstances usually resolves with treatment of the underlying disorder, and platelet transfusions are rarely necessary. Thrombocytopenia due to TTP, HUS, or heparin-induced thrombocytopenia (HIT) is more characteristically associated with microvascular occlusion or thrombosis than with bleeding (Table 158-1).

Immune-mediated platelet destruction can result from drugs, alloimmune sensitization, or autoimmunity. Medications should always be considered as a possible cause of acute thrombocytopenia. The list of potential offending agents is long, but drugs with strong evidence of antibody-mediated platelet destruction include quinine, quinidine, sulfonamides (such as trimethoprim-sulfamethoxazole), β-lactam antibiotics (both penicillins and cephalosporins), vancomycin, procainamide, and gold salts. In addition to stopping the offending medication, platelet transfusions might be required for severe thrombocytopenia.

Decreased Platelet Production

Decreased platelet production occurs in primary diseases of the bone marrow, such as acute leukemia and aplastic anemia; myelophthisic processes in which bone marrow is affected by metastatic carcinoma, fibrosis, or other clonal hematopoietic disorders; following toxin-induced (such as chemotherapy or ethanol exposure) or radiation therapy–induced myelosuppression; and during infections with viruses such as HIV, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and varicella. Thrombocytopenia also occurs when normal megakaryocyte proliferation is impaired by myelodysplasia.

Thrombocytopenia due to decreased platelet production is often accompanied by abnormalities of the white blood cells or red blood cells. This should be readily apparent by inspection of the CBC and review of the peripheral blood smear. When thrombocytopenia in this setting is accompanied by bleeding, the bleeding usually requires treatment by platelet transfusion. Additionally, when decreased platelet production is profound (less than 10,000/μL) and cannot be readily reversed, prophylactic platelet transfusion to prevent bleeding should be considered. However, as will be discussed in the following section, prophylactic platelet transfusion is problematic because of the short lifespan of platelets and the potential to develop alloantibodies that will limit the effectiveness of future platelet transfusions.

TABLE 158-1 DISORDERS THAT CAUSE BOTH THROMBOCYTOPENIA AND THROMBOSIS

Thrombotic thrombocytopenic purpura (TTP)
Hemolytic-uremic syndrome (HUS)
Heparin-induced thrombocytopenia (HIT)
Disseminated intravascular coagulation (DIC)
Paroxysmal nocturnal hemoglobinuria (PNH)
Vasculitis (such as systemic lupus erythematosus)
Antiphospholipid antibody syndrome

Platelet Sequestration

Approximately 30 to 40% of the circulating platelet mass is normally sequestered within the spleen. Enlargement of the spleen due to portal hypertension or infiltration is accompanied by expansion of the splenic platelet pool. Because hypersplenism by itself rarely causes a platelet count of less than 40,000/μL to 50,000/μL, bleeding due to thrombocytopenia from hypersplenism alone is unusual. In addition, if a patient with a large spleen has a platelet count of less than 40,000/μL, an additional etiology for the thrombocytopenia should be considered.

CLINICAL MANIFESTATIONS

In the absence of qualitative platelet defects (Chapter 159), excessive bleeding does not occur in thrombocytopenic patients following trauma or surgery unless the platelet count is lower than 75,000/μL. In otherwise hemostatically normal patients, spontaneous hemorrhage typically does not occur unless platelet counts are below 30,000/μL. Patients with platelet counts of less than 5000/μL to 10,000/μL are at a high risk for spontaneous, life-threatening hemorrhage. However, there is no absolute threshold for spontaneous bleeding due to thrombocytopenia. Bleeding may occur at higher counts when fever, sepsis, severe anemia, and other hemostatic defects are present, or when platelet function is impaired by medication. It is sometimes said that patients with wet purpura (mucocutaneous bleeding with blood blisters) are at particularly high risk for sudden catastrophic bleeding events. Therefore, it is critical that the physician consider the gamut of possibilities when diagnosing and managing a patient with a low platelet count.

DIAGNOSIS

Typically, the first step in diagnosing a patient with a low platelet count is to determine whether the thrombocytopenia is attributable to increased platelet destruction, decreased platelet production, or hypersplenism (Fig. 158-1). Since no single test can differentiate among the three possibilities, clinical evaluation is critical. A thorough history and physical examination, with attention to possible alternative explanations for thrombocytopenia, are mandatory. Particular attention should be paid to the duration of symptoms, which helps to determine whether the patient has acute or chronic thrombocytopenia. The clinician should also focus on the patient's recent exposure to new medications that might induce thrombocytopenia as a side effect.

Preliminary laboratory tests include a CBC with a differential, along with an examination of the peripheral blood smear (Chapter 143). Abnormalities in the number or morphology of the leukocytes or erythrocytes may indicate a systemic inflammatory disorder or a pathology within the bone marrow; fragmentation of red cells may suggest a microangiopathy such as thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), or disseminated intravascular coagulation (DIC). Clumping of the platelets on the peripheral blood smear may indicate that the patient has pseudothrombocytopenia (Chapter 157). This anomaly is usually due to an antibody that binds to and thereby agglutinates platelets only in the presence of hypocalcemia induced by ethylenediaminetetraacetic acid (EDTA) in the blood collection tube or when the blood sample is allowed to cool to room temperature. Repeating the platelet count in a blood sample that has been anticoagulated with heparin and kept warm until it is analyzed can help exclude this spurious diagnosis. Any additional testing to determine the cause of thrombocytopenia is based solely on the available clinical information derived from the history and examination of the patient. For example, testing for human immunodeficiency virus (HIV) would be prudent in a patient with risk factors. A bone marrow aspirate and biopsy are typically not required for a patient with thrombocytopenia who has an otherwise normal CBC and peripheral blood smear. However, a bone marrow aspirate and biopsy should be considered in older patients and in patients whose thrombocytopenia is progressive or in whom standard therapy has not been effective.

TREATMENT

For patients with decreased platelet production, the cornerstone of treatment is platelet transfusion (Chapter 162). For patients with other specific causes, however, platelet transfusions may or may not be a beneficial therapeutic option.

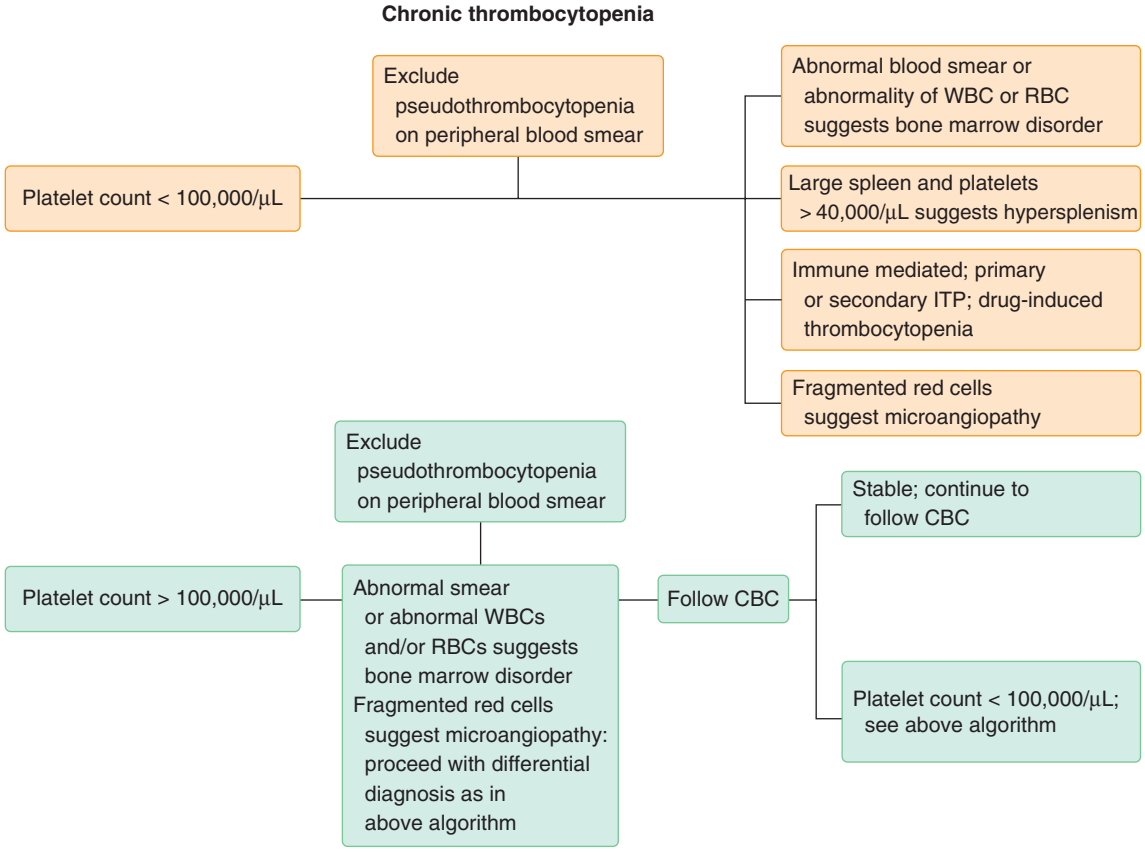

FIGURE 158-1. Systematic approach to the evaluation of chronic thrombocytopenia. CBC = complete blood count; ITP = immune (idiopathic) thrombocytopenic purpura; RBC = red blood cells; WBC = white blood cells.

FIGURE 158-2. Petechiae. Multiple pinpoint, nonblanching, erythematous macules found predominantly on skin of dependent extremities in patients with severe thrombocytopenia.

Platelet Transfusions

Clinicians usually consider "wet" bleeding to be much more ominous than "dry" bleeding. Signs of wet bleeding include epistaxis, gingival bleeding, gastrointestinal bleeding, genitourinary bleeding, and bleeding around intravenous sites. Dry bleeding is defined as ecchymosis or petechiae (Fig. 158-2). Overt wet bleeding that is clearly due to thrombocytopenia is usually treated with platelet transfusion (Chapter 162). Prophylactic platelet transfusion for patients who are not bleeding is controversial. When making the decision whether to treat a nonbleeding patient with thrombocytopenia, the practitioner must consider the short lifespan of platelets (10 days), the 5- to 7-day shelf life of stored platelets, and the potential for the patient to develop transfusion-induced platelet alloantibodies. In patients undergoing treatment for acute leukemia, clinical trials have supported the practice of prophylactic platelet transfusions when the platelet count is below 5000/μL or 10,000/μL, rather than waiting until bleeding occurs in the severely thrombocytopenic patient.[1]

The indications for prophylactic platelet transfusions before interventional procedures are predominantly based on clinical experience and expert opinions, rather than on clinical trials. Current guidelines recommend platelet transfusion in patients with therapy-induced hypoproliferative thrombocytopenia and a platelet count of less than 10,000/μL. Prophylactic platelet transfusion is also indicated for patients having elective central venous catheter placement with a platelet count less than 20,000/μL and for patients having elective diagnostic lumbar puncture or major elective nonneuraxial surgery with a platelet count less than 50,000/μL (Table 158-2).[2] Platelet transfusions should continue for several days following procedures where the risk for bleeding or the complications resulting from bleeding are high. For extremely high-risk procedures that involve the nervous and ocular systems, the prophylactic platelet transfusions should be continued for at least 7 to 10 days.

A donated unit of blood contains approximately 50 billion platelets. Infusing this number of platelets into a patient should increase his or her platelet count by 20,000/μL divided by the patient's body surface area in square meters. Therefore, transfusion of one unit into an average-sized adult patient should increase the individual's platelet count by approximately 10,000/μL to 12,000/μL. Bags of platelets used for transfusions are typically obtained by pooling platelets derived from four to six blood donors. Therefore, a "unit" at one hospital may be derived from more donors than a "unit" obtained at another hospital.

Large quantities of platelets can be derived from a single donor by using apheresis technology (plateletpheresis) (Chapter 162). Because there is minimal loss of red blood cells with this technique, plateletpheresis allows one individual to donate very large numbers of platelets (equivalent to the number of platelets obtained from 6 units of donated blood). The risk for platelet alloimmunization is partially dependent on the number of individuals donating platelets to a patient. Therefore, single-donor plateletpheresis can minimize the risk of alloimmunization. To minimize exposure to blood products (Chapter 162), a strategy of low-dose (110 billion/m^2) transfusions requires more frequent platelet transfusions but ultimately results in fewer transfused platelets without the risk of bleeding complications compared with higher-dose transfusions in patients who require prophylactic platelet transfusion therapy for hypoproliferative thrombocytopenia.[3]

Several complications of platelet transfusion therapy must be kept in mind (also see Chapter 162). First, some patients can become alloimmunized against platelet antigens and can become refractory to future platelet transfusion therapy (discussed in detail later). Second, bacterial contamination of stored

TABLE 158-2 SUGGESTED MINIMUM PLATELET COUNTS BEFORE INVASIVE PROCEDURES

VERY HIGH-RISK PROCEDURES—75,000/μL TO 100,000/μL
Neurosurgery
Ocular surgery (except cataract extraction)
Thyroid surgery
Prostatectomy
MODERATE-RISK PROCEDURES—50,000/μL

Dental extraction
Most surgical procedures
LOW-RISK PROCEDURES—30,000/μL
Endoscopy without biopsy
Bronchoscopy without biopsy
VERY LOW-RISK PROCEDURES—NO PLATELET TRANSFUSIONS NECESSARY
Bone marrow biopsy
Cataract extraction

platelets is a much more common complication than the infectious risk associated with red blood cell transfusions. Unlike red blood cells, which are stored frozen after being harvested from donated blood, platelets are sensitive to cool temperatures and therefore need to be stored at room temperature. This method of storage results in more bacterial overgrowth in the transfusion bags. Transfusion-associated bacterial sepsis is one of the most frequently reported causes of transfusion-induced mortality in the United States, and platelet transfusions are the most common blood products associated with sepsis. In contrast to the risk for bacterial infection, the risk for viral infection from platelet transfusions is no higher than it is for red blood cell transfusions. From a single unit of platelets, the risk for being exposed to HIV is less than 1 in 1.5 to 2 million, the risk for exposure to hepatitis B virus is less than 1 in 200,000, and the risk for exposure to hepatitis C virus is less than 1 in 1 to 2 million.

For thrombocytopenia caused by TTP or HIT, there is usually no indication for platelet transfusions because thrombosis occurs much more frequently than hemorrhage in these disorders. However, platelet transfusions may be considered under expert oversight for patients who have profound thrombocytopenia with life-threatening hemorrhage.

The Transfusion-Refractory Patient

Many patients do not have an optimal increase in their platelet count following transfusion. Although there are various definitions of platelet refractoriness, it is simplest to base this definition on the timing of platelet loss following transfusion. Patients who do not have the predicted rise in their platelet count (between 10,000/μL and 12,000/μL for every unit of donated platelets) should have their platelet count analyzed before their next platelet transfusion, 1 hour after that transfusion, and again 24 hours later. If their platelet count rises appropriately 1 hour after the transfusion but falls substantially 24 hours later, the patient has ongoing platelet consumption. This is often seen in patients with sepsis, DIC, severe active hemorrhage, or sometimes drug-mediated immune destruction of platelets. In these situations, the best therapy is to treat the underlying cause and to continue to support the patient with platelet transfusions as clinically indicated. Alternatively, some patients fail to have a significant increase in platelets even 1 hour after a transfusion. These patients may have hypersplenism, an autoantibody that eliminates not only endogenous platelets but also allogeneic donor platelets (as seen in patients with ITP or some patients with drug-mediated immune destruction of platelets), or alloantibodies that react with antigens on the transfused platelets.

Alloantibodies develop in approximately 20% of patients who are repeatedly exposed to platelet transfusions, and these patients present some of the most challenging management issues in transfusion medicine (Chapter 162). The alloantibodies may be directed against human leukocyte antigen (HLA) class I antigens (HLA-A and HLA-B) or against platelet-specific antigens present on the surface of the platelets. Because it appears that HLA class II antigens present on the surface of leukocytes are essential for the development of antibodies directed against HLA class I antigens, efforts to remove the contamination of leukocytes in platelet transfusion preparations can minimize alloantibody formation. Therefore, filters that trap leukocytes during transfusions are useful to prevent patients from becoming refractory to future platelet transfusions. After a patient develops alloantibodies against transfused platelets, the clinician and the blood bank should attempt to identify whether the alloantibody is directed against an HLA class I antigen or against a platelet-specific antigen. If the alloantibody can be identified, platelets derived from donors matched for an HLA class I antigen or the platelet-specific antigen can be used. Corticosteroids, intravenous immunoglobulin, splenectomy, and recombinant factor VIIa are probably of no value in maintaining hemostasis in platelet-refractory thrombocytopenic patients. Antifibrinolytic agents (e.g., ε-aminocaproic acid) under expert oversight might be helpful for patients with bleeding that is predominantly in the oral cavity or in the genitourinary tract. However, antifibrinolytic agents are contraindicated in patients with DIC (Chapter 161) because these agents can precipitate thrombotic events.

SPECIFIC CAUSES OF THROMBOCYTOPENIA

Drug-Induced Thrombocytopenia

PATHOBIOLOGY

Drug-induced thrombocytopenia is one of the most frequent causes of cytopenias evaluated by physicians.[4] Typically, drug-induced thrombocytopenia is the result of an immune reaction elicited by either the drug or by one of its metabolites. Sometimes the drug is simply deposited on the platelet surface, and antidrug antibodies lead to accelerated platelet clearance, primarily in the spleen. More frequently, the drug binds to a protein on the platelet surface and alters the conformation of the platelet protein in a way that is ultimately targeted by the immune system. In the absence of the drug or drug metabolites, this platelet neoantigen disappears, and the thrombocytopenia slowly resolves as new platelets are released from the bone marrow. Immune-mediated platelet destruction explains most drug-induced thrombocytopenias, but there are some exceptions. For example, chemotherapy and other bone marrow toxins can decrease platelet production and thereby induce thrombocytopenia by a mechanism independent of the immune system.

CLINICAL MANIFESTATIONS

The thrombocytopenia induced by medications can have a mild, moderate, or even severe course. Almost all types of drug-induced thrombocytopenia predispose the patient to the risk of hemorrhagic but not thrombotic complications. The notable exception to this rule is heparin-induced thrombocytopenia (discussed separately in the next section). A common difficult clinical situation occurs when an infected or otherwise critically ill patient develops abrupt thrombocytopenia. In this situation, it can be difficult to discern whether the thrombocytopenia is the result of the recent illness (such as a bacterial or viral infection) or its treatment (such as an antibiotic or another unrelated medication). It is also frequently challenging to discern drug-induced thrombocytopenia from ITP. For this distinction, the patient's medical history may be helpful. A gradually progressive thrombocytopenia over months to years is more consistent with ITP than with thrombocytopenia that is induced by a medication. Conversely, the rapid onset of thrombocytopenia following the initiation of a new medication indicates that the drug is the most likely culprit. The time between the initiation of the offending drug and the development of thrombocytopenia has not been well documented for most medications. However, thrombocytopenia typically begins days to a few weeks after the administration of most medications with this type of toxicity. Presumably, this lag time represents the period required for the patient to develop an immune response against the drug-platelet complex. Medications that have been taken safely for years before the onset of thrombocytopenia are unlikely to be the offending agents. In addition to an assessment of the patient's prescribed medications, a careful and comprehensive evaluation of the patient's over-the-counter medications is also necessary. Agents that contain quinine lead the list of often nonprescribed drugs that can induce life-threatening thrombocytopenia. Quinine is frequently contained in over-the-counter pills for leg cramps. Even the quinine in tonic water can induce severe thrombocytopenia ("gin and tonic purpura") when ingested by certain patients, since a drug-induced, immune-mediated thrombocytopenia usually is not related to the dose of the offending drug.

DIAGNOSIS

Some medications are much more likely to induce thrombocytopenia than others. Table 158-3 contains a partial list of drugs that frequently induce this type of toxicity. One particularly useful online database (www.ouhsc.edu/platelets/ditp.html) lists and periodically updates the level of evidence for specific drugs that may induce thrombocytopenia. With the exception of tests for HIT, laboratory tests for drug-induced thrombocytopenia do not have widespread applicability. Usually, drug-induced thrombocytopenia is proved

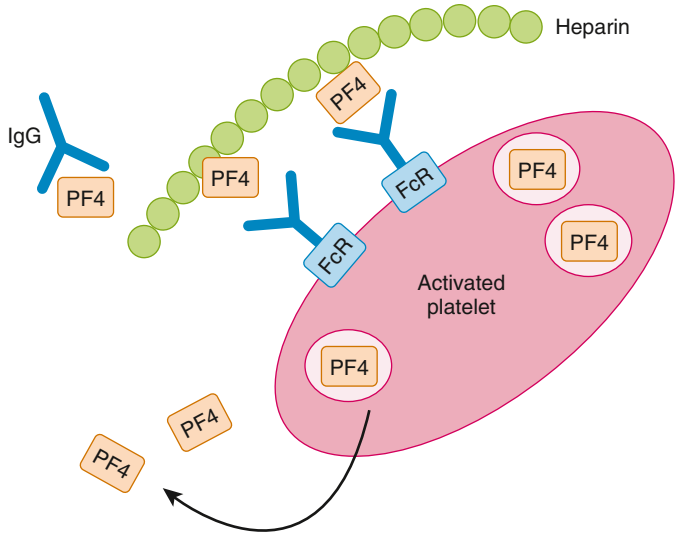

FIGURE 158-3. Pathophysiology of heparin-induced thrombocytopenia. Platelet factor 4 (PF4) is a protein that is stored in platelet granules and that is secreted from platelets upon their activation. Heparin can bind to PF4 and induce a conformational change within PF4 that in some patients produces an antibody-mediated immune response. Large complexes of immunoglobulin (Ig), heparin, and PF4 can accumulate on the platelet surface and stimulate the platelet when the Fc portion of the antibody interacts with the platelet's FcγRII receptor (FcR). Once activated, the platelets contribute to thrombosis. Additionally, the activated platelets secrete more PF4, which perpetuates the process.

only in retrospect, when the platelet count rises after the discontinuation of the suspected medication. Even then, the diagnosis is not conclusive unless thrombocytopenia recurs after rechallenging the patient with the offending drug (a practice that is almost never recommended).

TREATMENT

The best method for treating drug-induced thrombocytopenia is to stop all suspected offending medications.[5] Usually, no additional therapy is indicated. The thrombocytopenia typically begins to resolve without further intervention within days to a week of stopping the drug. The notable exceptions involve drugs with particularly long half-lives. Sulfonamides, quinine, and quinidine are notorious for inducing severe or even life-threatening thrombocytopenia. In patients with profound thrombocytopenia (<10,000/μL to 15,000/μL) or at a high risk for bleeding, platelet transfusions are indicated. When ITP cannot be confidently excluded and the thrombocytopenia is life-threatening, specific treatment for ITP can also be initiated (see later in this chapter).

HEPARIN-INDUCED THROMBOCYTOPENIA

EPIDEMIOLOGY

A special case of drug-induced immune-mediated thrombocytopenia associated with arterial and venous thrombosis, rather than bleeding, is heparin-induced thrombocytopenia (HIT).[6,7] It is seen in 2 to 5% of patients exposed to unfractionated heparin and in 0.7% of patients given low-molecular-weight heparin. HIT almost never occurs in patients who are exposed only to fondaparinux.

PATHOBIOLOGY

Platelets can secrete a protein called platelet factor 4 (PF4) that can bind to heparin. HIT is caused by an antibody that binds to this PF4-heparin complex (Fig. 158-3). Large complexes of antibodies directed against heparin-bound PF4 accumulate on the surface of platelets. At times, these anti-PF4 immunoglobulins bind to Fc receptors that are also present on the platelet surface, leading to activation of the platelet, release of more PF4, and a cycle of events that causes the stimulation of even more platelets. Ultimately, this also leads to the activation of the coagulation cascade, likely through exposure of tissue factor on the surface of activated macrophages. The activation of platelets and the clotting cascade results in the formation of both thrombi and thrombocytopenia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Given the extensive use of heparin in hospitalized patients, HIT must always be considered when thrombocytopenia develops in this setting. However, patients with this syndrome often have multiple potential causes of thrombocytopenia, such as infections or other medications, so it is important to consider these other causes. Large retrospective studies of HIT have suggested that the onset of thrombocytopenia relative to the initiation of heparin therapy is useful in establishing or excluding this diagnosis. Immune-mediated HIT typically occurs 5 to 14 days after patients are given heparin by any route. HIT can even occur after subcutaneous injections of "minidose" heparin or following extremely low doses by heparin flush of intravenous lines. The 5- to 14-day lag between heparin exposure and the appearance of HIT is due to the time it takes for the immune response to generate the requisite antibodies against the heparin-PF4 complex. Some patients who have been exposed to heparin within the past several months may already have preexisting antibodies against the heparin-PF4 complex in their circulation. Therefore, when these patients are re-exposed to heparin, they may develop an acute onset of HIT even within the first day of the reinitiation of heparin. Whether or not pre-exposed to heparin, however, platelet-activating HIT antibodies are detectable at the onset of the HIT-related platelet count fall.

The unique timing of acute-onset HIT within hours of heparin re-exposure and the more typical development of HIT within 4 to 14 days of initial heparin exposure emphasize the importance of conducting a careful and critical history in establishing the diagnosis. HIT should be suspected in any patient who develops thrombocytopenia while on heparin therapy. Since the normal platelet count varies widely (140,000/μL to 450,000/μL), some patients may have a substantial decrease in their platelet count but still remain within the normal range. Therefore, a greater than 50% decrease in the platelet count of a patient on heparin should raise the suspicion of this syndrome. HIT should also be suspected in any patient who develops a thrombotic event while on heparin therapy. Some have used the 4 T scoring system to clinically assess the likelihood of HIT, as opposed to a different cause of thrombocytopenia. The 4 T score uses a combination of platelet count fall, timing of platelet count fall, coexisting occurrence of thrombosis, and other potential causes of thrombocytopenia to arrive at a clinical likelihood of HIT that is low probability, intermediate probability, or high probability.

Although antibodies against the heparin-PF4 complex are almost always present in patients with HIT, these antibodies are also frequently present in heparin-treated patients who do not have this disorder (i.e., those patients with neither thrombocytopenia nor thrombosis). There are two general categories of laboratory assays for the diagnosis of HIT: functional assays and immunologic assays (Table 158-4). Functional assays analyze whether the combination of heparin and the patient's plasma can induce normal platelets to aggregate or to secrete serotonin; these assays have very high specificity but relatively low sensitivity.[8] Immunologic assays test the patient's plasma for antibodies that bind to the heparin-PF4 complex; these assays have very high

TABLE 158-4 LABORATORY ASSAYS FOR HEPARIN-INDUCED THROMBOCYTOPENIA

ASSAY	SENSITIVITY (%)	SPECIFICITY (%)
Functional assay (e.g., serotonin release assay)	56-100%	>95%
PF4/heparin enzyme immunoassay (ELISA)	99%	30-70%

ELISA = enzyme-linked immunosorbent assay; PF4 = platelet factor 4.

sensitivity but lack specificity. Some studies show a good correlation between the amount of anti-PF4 antibodies present (such as determined by the optical density of an ELISA-based immunoassay) and the chance that the patient has clinically meaningful HIT. A *negative immunologic assay* is extremely useful in excluding this diagnosis, and a *positive functional assay* is useful in confirming the diagnosis of HIT. Several days may elapse before the test results are available. Therefore, in practice, these laboratory assays provide only confirmatory information. Urgent clinical decisions should *not* be deferred until such test results are available. The timing of the thrombocytopenia with respect to the heparin exposure and the degree of the platelet drop are the most important pieces of information needed by the physician when evaluating a patient suspected of having HIT.

Because platelets are consumed as they become activated, the clinical presentation of HIT is thrombocytopenia. However, it is unusual for the thrombocytopenia to actually cause bleeding in patients with HIT. Instead, HIT is a highly prothrombotic disorder. Both venous and arterial thromboses are common in HIT. Patients with HIT who do not have thrombosis on initial presentation still have a 20 to 30% chance of developing a thrombus within the next month. Nevertheless, the incidence of HIT-related clinical events is greatest immediately after diagnosis. More importantly, clinical studies report that the cessation of heparin alone frequently fails to prevent the development of new thrombotic events.

TREATMENT AND PREVENTION

If a patient is suspected of having HIT, all heparin should be stopped immediately. This includes subcutaneous injections of "minidose" heparin, heparin flushes of intravenous lines, and low-molecular-weight heparin; even heparin-coated intravenous catheters should be withdrawn. Alternative anticoagulation, such as the direct thrombin inhibitor argatroban, should be used (Chapter 70). Although not as well studied (nor FDA approved), both bivalirudin and fondaparinux appear to be viable alternatives. Accumulating evidence also suggests that the direct-acting oral anticoagulants (Table 70-6) can be used in patients with HIT,[9] using doses similar to what are used for the treatment of an acute venous thromboembolism but with a higher dose administered at the beginning of therapy (e.g., rivaroxaban 15 mg twice daily with food for 21 days then 20 mg with food once per day). Warfarin should not be used initially in cases of acute HIT because of its delayed therapeutic effect and its association with venous limb gangrene. However, when the platelet count has returned to a normal level as the acute episode of HIT starts to resolve, warfarin can be slowly introduced at a dose of 5 mg or less daily while an alternative anticoagulant such as argatroban is still being used. The warfarin dose can be gradually increased to achieve an international normalized ratio (INR) of 2 to 3. If the patient has had an acute thrombosis attributable to their HIT, they should be treated for a minimum of 3 months of anticoagulation. If the patient has thrombocytopenia but no thrombosis, anticoagulation is usually given for 4 to 6 weeks. Because patients rarely become profoundly thrombocytopenic as a result of HIT alone, platelet transfusions are typically not required and may actually precipitate thrombotic complications.

If low-molecular-weight heparin is used for prophylaxis instead of unfractionated heparin, the risk of HIT is much lower. However, low-molecular-weight heparins should never be used in the treatment of HIT because this drug can cross-react with the pathologic HIT antibodies.

CORONAVIRUS-2019

Coronavirus-2019 (COVID-19) infection (Chapters 335, 336, and 337) or vaccination against it can rarely result in immune thrombotic thrombocytopenia caused by platelet-activating antibodies against platelet factor 4.[10,11] The clinical manifestations are similar to autoimmune heparin-induced thrombocytopenia, with a predilection for venous thrombosis, pulmonary embolism, and cerebral venous sinus thrombosis.[12] The treatment is anticoagulation, but the precise best regimen is not currently known.

SEPSIS

Along with the exposure to certain drugs, bacterial and viral infections are among the most common causes of acute thrombocytopenia in hospitalized patients. Acute thrombocytopenia can be caused by the deposition of antibody-antigen complexes on the platelet surface through an "innocent bystander" phenomenon. These antibody-coated platelets are then cleared from the circulatory system by Fc receptor–expressing macrophages in the spleen. Thrombocytopenia associated with infections can also be due to DIC (as discussed in Chapter 161). It is notable that patients who are infected with severe acute respiratory syndrome coronavirus 2 (Chapter 334) usually have normal or elevated platelet counts despite having high D-dimer levels like patients with DIC. The treatment of sepsis-induced thrombocytopenia is directed at treating the underlying cause, along with the administration of platelet transfusions as clinically indicated.

IMMUNE THROMBOCYTOPENIC PURPURA

DEFINITION

ITP is an autoimmune disorder caused by circulating antiplatelet autoantibodies. An ITP-like picture can also be found in patients with autoimmune diseases, such as in systemic lupus erythematosus (Chapter 245); in low-grade lymphoproliferative disorders, such as chronic lymphocytic leukemia (Chapter 169); and in HIV infection (Chapter 359).

CLINICAL MANIFESTATIONS

ITP was classically thought to be a disease of young women. Although this description is appropriate for many individuals with this disorder, it is now appreciated that ITP can occur in patients of either sex and at any age. ITP is a chronic, recurring disorder in most adults, in stark contrast to pediatric patients, who usually suffer from acute ITP and much less frequently have chronic thrombocytopenia.

In contrast to patients with coagulation factor deficiencies who present with bleeding deep within their tissues, individuals with ITP (or other platelet disorders) typically have excessive mucocutaneous bleeding. Consequently, the clinician should inquire whether the patient has noticed epistaxis, gingival bleeding, easy bruising, hematuria, melena, or hematochezia. Female patients should also be asked about irregular or excessive vaginal bleeding. The physical examination should pay particular attention to signs of mucocutaneous bleeding. The patient should be thoroughly examined for petechiae (see Fig. 158-2) and ecchymosis as well as for evidence of hemorrhage within the conjunctiva, retina, and central nervous system.

DIAGNOSIS

In patients with ITP, the CBC is usually normal except for the thrombocytopenia, and their peripheral blood smear is remarkable only for a decreased number of platelets, some of which may be larger than normal. Splenomegaly is absent unless the ITP is due to an underlying disorder, such as lymphoma that is associated with splenomegaly. A bone marrow examination is usually not necessary in the absence of abnormalities other than thrombocytopenia on the CBC and peripheral blood smear. If performed, the bone marrow aspirate and biopsy of ITP patients typically show normal or increased numbers of megakaryocytes. However, the rest of their bone marrow is otherwise normal. These bone marrow findings are similar to what is observed in the bone marrows of patients who have other forms of destructive thrombocytopenia such as drug-induced thrombocytopenia. Antiplatelet antibody assays are neither sensitive nor specific and therefore should not be done. ITP must be distinguished from the rare syndrome of cyclic thrombocytopenia in which platelet counts spontaneously rebound, and bleeding, even at the nadir of the platelet count, tends to be mild.[13]

TREATMENT

First-Line Treatment

Initial management of ITP is guided by both symptoms and platelet count (Table 158-5).[14] Asymptomatic patients with platelet counts >30,000/μL can be followed without treatment.[15] If the patient is bleeding or has a platelet count <30,000/μL, either prednisone (1 mg/kg orally daily) or high-dose dexamethasone (4-day pulses of 40 mg intravenously per day every 28 days for several cycles) are both effective (Table 158-6), with a few trials showing better results with dexamethasone, and others (including the largest trial) showing no difference in long-term response rates.[A1] Oral prednisone has the advantage of allowing the dose to be titrated according to the platelet count. Although corticosteroids remain the first-line therapeutic modalities, mycophenolate mofetil under expert supervision is emerging as another first-line option.[A2]

TABLE 158-5 WHO SHOULD BE TREATED FOR IMMUNE THROMBOCYTOPENIC PURPURA (ITP)?

Guidelines for treatment of adult patients with ITP include the following recommendations:

1. Treatment should be administered to newly diagnosed patients if platelets are <30,000/μL.
2. First-line treatment should be a longer course of corticosteroids. IVIG should be used with corticosteroids when a more rapid increase in platelet count is required. Either IVIG or anti-D (where appropriate) should be used as first-line treatment if corticosteroids are contraindicated. If IVIG is used, the dose should be 1 g/kg once a day for 2 consecutive days.
3. Recommended second-line treatment in patients who are unresponsive to or relapse after the initial course of corticosteroids should be rituximab or a thrombopoietin receptor agonist. Splenectomy can be considered if treatment has been required for more than a year since it can produce lifelong responses in some patients.

IVIG = intravenous immunoglobulin.

TABLE 158-6 THERAPY FOR THE INITIAL MANAGEMENT OF IMMUNE THROMBOCYTOPENIC PURPURA

ORAL CORTICOSTEROIDS	
The effect is dose dependent—approximately 80% of patients respond to 1 mg/kg/day. Toxicity also increases with the dose and duration of treatment, and side effects include glucose intolerance, immunosuppression, osteoporosis, and cataracts. Relapse is typical once therapy is tapered and discontinued. High-dose dexamethasone (40 mg/day for 4 days) has been reported to have a higher initial response rate and may be generally better tolerated than prednisone 1 mg/kg/day for 4 weeks followed by taper as initial first-line therapy.	
INTRAVENOUS IMMUNOGLOBULIN	
The effect is more rapid than daily prednisone. Administered at a dose of 1 g/kg/day for 2 consecutive days or 0.4 g/kg/day for 5 consecutive days. The response rates are approximately 80%, and the effects typically last 2 to 4 weeks. Toxicity includes headache, allergic reactions, and rarely, thrombosis.	
ANTI-D IMMUNOGLOBULIN	
It is administered at a dose of 50 to 75 μg/kg intravenously and should only be given to patients who have an Rh+ blood group. The response rates are dose dependent but can approach 75 to 80%. Hemolysis is a common toxicity but is usually mild. Rarely, hemolysis can be life threatening and can be associated with disseminated intravascular coagulation, renal failure, and end-organ infarction. It is generally ineffective in patients who have failed splenectomy.	

TABLE 158-7 THERAPY FOR THE MANAGEMENT OF REFRACTORY IMMUNE THROMBOCYTOPENIC PURPURA

ORAL PREDNISONE	
The effect is dose dependent and rapidly dissipates after discontinuation of the medication. Some patients can be maintained on a very low and tolerable daily dose (e.g., 5 mg). Long-term use is associated with infections, diabetes, osteoporosis, avascular necrosis, weight gain, and cataracts.	
ORAL DEXAMETHASONE	
This is administered at a dose of 40 mg/day for 4 consecutive days, repeated every 2 to 4 weeks for several months. Sustained response rates of 29 to 42% have been reported, although response rates are widely believed to be lower. Toxicity is similar to that of oral prednisone.	
SPLENECTOMY	
Durable (often lifelong) significant responses are seen in 65 to 70% of patients who undergo this procedure. More modest benefits are seen in another 10 to 15% of patients. There is no useful way to predict who will respond. Splenectomy is associated with surgical morbidity and some mortality (≈1-2%). Splenectomy produces lifelong immunosuppression to encapsulated and gram-positive organisms. Splenectomy is also associated with a small long-term risk of thrombosis.	
RITUXIMAB	
This is given at a dose of 375 mg/m^2/wk intravenously for a total of 4 weeks. Significant responses are seen in up to 60% of patients, and these responses typically last for months. Toxicity includes reactivation of hepatitis B, immunosuppression, and rarely, progressive multifocal leukoencephalopathy.	
THROMBOPOIETIN RECEPTOR AGONISTS	
These are administered daily (eltrombopag and avatrombopag) or weekly (romiplostim). An effect typically starts to be seen in 2 to 3 weeks and disappears shortly after the discontinuation of the medication. However, sustained, long-term effectiveness has been demonstrated while on the drug. Toxicity from long-term use is not well known but may include excessive thrombosis and bone marrow fibrosis.	

Second-Line Treatment

Rituximab, a "humanized" murine monoclonal antibody against CD20 (a B-cell antigen), is widely used in patients who are unresponsive to first-line therapy. Complete response rates are seen in approximately 40% of patients, and meaningful response rate with platelet counts above 50,000/μL are seen in approximately 60% of patients. The combination of rituximab (375 mg/m^2 intravenously weekly for 4 weeks) plus dexamethasone (40 mg per day orally for 4 days) can induce higher response rates and longer time to relapse than dexamethasone alone.[16] However, the risk of grade 3 to 4 adverse events is increased when rituximab is combined with dexamethasone. Since the effect of rituximab usually requires 3 or more weeks, another therapy (such as corticosteroids) should be used initially if the patient is profoundly thrombocytopenic.

Peptides have been developed that bind to and activate the thrombopoietin (TPO) receptor; these agents are called TPO receptor agonists or thrombopoiesis stimulating agents. Because these recombinant drugs bear little structural similarity to native TPO, they do not trigger autoimmune anti-TPO antibodies. The FDA has approved two of these drugs, and several more are being used in other countries.

Romiplostim is a TPO receptor agonist composed of several copies of a receptor–binding peptide spliced into a recombinant antibody; it competes with endogenous TPO for binding to the TPO receptor and activates the receptor as would endogenous TPO.[A3] It is usually initiated at 2 to 3 μg/kg subcutaneously weekly, then slowly escalated to 10 μg/kg per week if needed. Eltrombopag[A4] and avatrombopag also activate the TPO receptor and improve thrombocytopenia and have the advantage of being administered orally. Eltrombopag is initiated at 50 mg orally daily (25 mg once daily in individuals with liver insufficiency or of East Asian ancestry), whereas avatrombopag is initiated at 20 mg orally per day. Subcutaneously administered romiplostim, orally administered eltrombopag, and orally administered avatrombopag are all capable of increasing platelet counts in approximately 70 to 90% of patients with ITP.[A5]

Remarkably, these drugs can also increase the platelet counts of patients whose ITP is refractory to other treatment modalities, including splenectomy. However, adverse events, including bone marrow fibrosis and thromboembolism, have been reported. Unfortunately, these drugs' effects disappear soon after their discontinuation.

Fostamatinib, which is an oral inhibitor of Syk kinase (dosed at 100 mg twice daily, increasing to 150 mg twice daily if the platelet count remains below 50,000/mL after 4 weeks of therapy), can be useful in patients who have not responded to multiple other therapies.[A6] It results in a 40 to 45% initial response rate and 18% stable response rate with continuous therapy in previously treated patients with chronic immune thrombocytopenia. Side effects include diarrhea, nausea, hypertension, and neutropenia.[17]

Refractory ITP

Refractory patients may require immunosuppressive medications or splenectomy (Table 158-7). Immunosuppressive options include immunomodulating agents, such as intravenous immunoglobulin (IVIG), anti-Rh immunoglobulin (anti-D), cyclophosphamide, azathioprine, cyclosporine, mycophenolate mofetil, dapsone, interferon, and etanercept.[18]

Splenectomy can provide a durable complete response in approximately 66 to 70% of patients.[19,20] Approximately half of the remaining patients who do not have normal platelet counts following splenectomy achieve a partial response that is clinically meaningful. Unfortunately, 10 to 15% of patients derive no benefit from splenectomy. There is no test to predict whether a particular patient will respond to this treatment, although initial steroid responders and younger patients tend to have a better outcome. It should be noted that splenectomy is associated with small long-term risks of both infections and thrombosis (Chapter 154).

Patients who have ITP with severe thrombocytopenia (<5000/μL) or internal bleeding should be promptly treated with both high doses of pulse corticosteroids and IVIG. Platelet transfusions may be given concurrently with IVIG for critical bleeding.

THROMBOTIC THROMBOCYTOPENIC PURPURA

DEFINITION

Thrombotic thrombocytopenic purpura (TTP) is a consumptive thrombocytopenia associated with a mechanical hemolytic anemia.[21] The classic pentad

of symptoms, which are thrombocytopenia, anemia, fever, neurologic problems, and renal abnormalities, are fully present in less than 10% of patients. Many patients today have only hemolytic anemia and thrombocytopenia. A good working definition for this diagnosis is thrombocytopenia along with a microangiopathic hemolytic anemia that is not associated with acute renal failure at presentation, disseminated intravascular coagulation, or another apparent cause. The poor specificity of the clinical features of this disease and the nonspecific laboratory abnormalities historically made TTP difficult to diagnose, but this has improved with the availability of ADAMTS13 testing. In the past, patients with untreated TTP had a mortality rate of 90% within 3 months. With modern therapy, patients with TTP have a mortality rate of approximately 10 to 20%.

PATHOBIOLOGY

Vascular endothelial cells normally secrete von Willebrand factor (vWF) (Chapter 159) that is composed of a large range of multimer sizes, including the so-called "ultralarge multimers." These latter forms bind to platelets very tightly even at low shear forces and therefore have the potential to create platelet aggregates in the circulation that might form microvascular occlusive thrombi, an undesirable result of vWF circulating with ultralarge multimers. However, a metalloproteinase identified as ADAMTS13 (*a d*isintegrin-like *a*nd *m*etalloprotease with *t*hrombospondin type 1 motif, member 13) is also normally present in blood and acts to cleave the ultralarge multimers of vWF, thereby preventing the formation of microvascular occlusions by platelet aggregates.[22] Most patients with adult-onset TTP have autoantibodies against ADAMTS13, thus causing an acquired deficiency of the enzyme and thereby permitting the circulation of thrombogenic ultralarge vWF multimers. Rare patients with inherited and recurrent TTP (Upshaw-Schulman syndrome) have a congenital deficiency of ADAMTS13.[23] Inherited or acquired ADAMTS13 deficiency causes the accumulation of ultralarge multimers of von Willebrand factor in plasma, which leads to platelet activation and the microvascular thrombosis that is characteristic of TTP (Fig. 158-4).

Characteristically, the thrombotic occlusions are in small terminal arterioles and capillaries and are composed mainly of platelets and von Willebrand factor within the damaged vascular lumen. In contrast to the pathology usually found in typical blood clots, the occlusions found in TTP patients contain very little fibrin and are referred to as hyaline thrombi.

Clinical assays of ADAMTS13 enzymatic activity are useful in diagnosing TTP. However, many patients can have a partial deficiency of ADAMTS13 without having TTP, so the absolute amount of deficiency is important. Levels of ADAMTS13 below 10% of normal are highly suggestive of TTP, while levels greater than 30% strongly argue against this diagnosis. Levels between 10 and 30% of normal are not very helpful.

Some patients reportedly developed TTP soon after taking an antiplatelet drug of the thienopyridine class. For example, clopidogrel can induce TTP, but the incidence is rare, about 1 in 250,000. Because the incidence of TTP in the general population is approximately 1 in 100,000, it is difficult to determine whether there is a significant risk for TTP in patients who are prescribed clopidogrel. The thienopyridine-derivative prasugrel has also been implicated in rarely causing TTP. Some patients have been diagnosed with TTP that was attributed to medications that directly injure the vascular endothelium (such as cyclosporine or tacrolimus). Most of these patients do not have TTP but have the related disorder HUS, discussed later in this chapter.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In TTP, patients can occasionally present with symptoms of excessive mucocutaneous bleeding, but they might also present with signs of a thrombotic event (including phlebitis, myocardial infarction, or stroke).[24] Abdominal pain is present in some patients, which is presumably due to intestinal ischemia. Signs of central nervous system disease, somnolence, and even coma can also be seen on presentation.

The two major hallmarks of TTP are microangiopathic hemolytic anemia and thrombocytopenia.[25] Microangiopathic hemolytic anemia is a non-immune-mediated hemolytic anemia caused by red cell fragmentation (Chapter 146). Patients with this disorder have typical laboratory findings of hemolytic anemia, including a high lactate dehydrogenase (LDH) level, elevated indirect bilirubin, low haptoglobin, and an increased reticulocyte count. Examination of the peripheral blood smear (Chapter 143) shows torn or fragmented red blood cells (schistocytes), and frequently also shows early red blood cell precursor cells (nucleated red blood cells). The thrombocytopenia may be mild if the disease is diagnosed at an early stage, but advanced cases of TTP can have platelet counts of less than 10,000/μL. Unlike most patients with typical thrombocytopenia, who tend to bleed excessively, patients with TTP have few hemorrhagic complications. Instead, they are markedly predisposed to thrombosis. In fact, a thrombotic complication in a thrombocytopenic patient is an important clue that TTP might be the cause of the thrombocytopenia (see Table 158-1). In the absence of plasmapheresis, TTP typically progresses and causes renal disease, neurologic symptoms, and fever. Since TTP now is often diagnosed in its early stages, patients usually only have microangiopathic hemolysis and thrombocytopenia.

TREATMENT

The prompt initiation of plasma exchange (plasmapheresis with plasma replacement) reduces the mortality rate associated with TTP from 90% to approximately 15%.[26] The mechanism of this benefit is partially due to the replacement of ADAMTS13. A randomized trial demonstrated that plasma exchange is more beneficial than plasma infusion for the treatment of TTP. This implies that some of the benefit of plasmapheresis is attributable to the removal of a pathologic substance from the patient's plasma. Assuming that the pathogenesis of most acquired forms of TTP is the antibody-mediated inhibition of ADAMTS13, plasma exchange has two benefits. First, it helps to remove the pathogenic antibody from the plasma. Second, the normal plasma infused into the patient during plasmapheresis repletes the deficiency of ADAMTS13.

Because patients with TTP can develop sudden thrombotic events (including stroke and myocardial infarction), and because patients can deteriorate quickly, it is prudent to initiate plasma exchange as rapidly as possible. Given the morbidity and mortality of untreated TTP, and given the relatively low risk of administering plasmapheresis, this therapy should be initiated even when

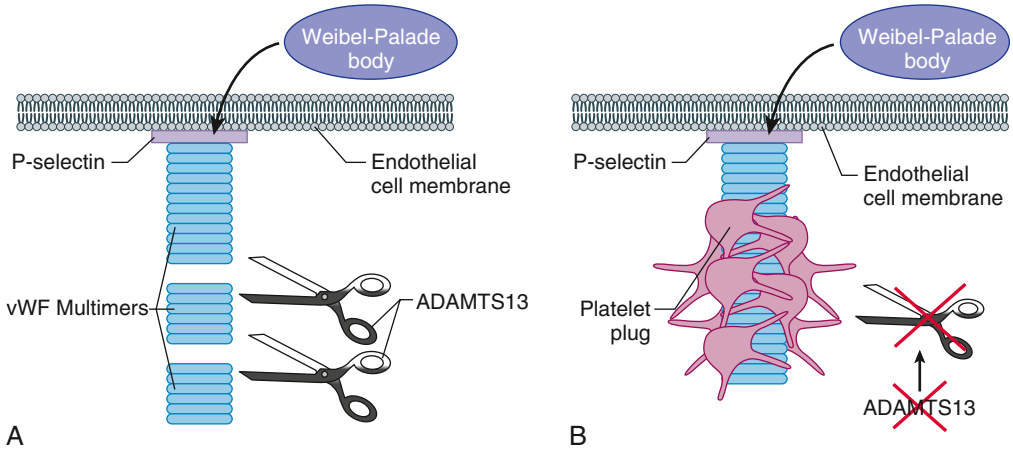

FIGURE 158-4. Pathophysiology of thrombotic thrombocytopenia purpura (TTP). A, Von Willebrand factor (vWF) is synthesized in endothelial cells and stored in Weibel-Palade bodies. The vWF is assembled into ultralarge multimers that are cleaved after they are released into the blood stream by the protease ADAMTS13. The resultant smaller multimers of vWF only bind to platelets to participate in normal hemostasis. **B,** Most patients with TTP have severe deficiency of ADAMTS13 (less than 10% of normal). This results in the accumulation of ultralarge multimers of vWF within the circulation, which promote the excessive adhesion of platelets. The consequence is the formation of large plugs composed of vWF and platelets that can cause vascular occlusions.

the diagnosis is not certain and without waiting for the results of ADAMTS13 testing. Plasmapheresis is not beneficial in children with Shiga toxin–induced HUS or in patients who develop HUS following their exposure to endothelium-toxic drugs, such as chemotherapy or calcineurin inhibitors (e.g., cyclosporine or tacrolimus).

Plasma exchange is administered to replace one entire plasma volume. An average-sized individual requires 20 to 30 units of fresh-frozen plasma for each plasmapheresis session. Therapy is usually administered daily, and patients are monitored for signs of improvement in their thrombocytopenia, hemolysis, neurologic symptoms, fever, and renal disease. Appropriate daily laboratory tests to monitor the patient are CBC, LDH, reticulocyte count, and creatinine. After the thrombocytopenia and hemolysis have been corrected for a few days, the daily plasmapheresis can either be discontinued or continued every other day for several more days. Most patients with TTP will start to respond within 3 to 5 days. A typical duration of therapy is 1 to 2 weeks, although some patients require treatment far beyond this usual time course.

A glucocorticoid is usually initiated at the start of treatment to decrease the production of anti-ADAMTS13 antibodies. Typically prednisone 1 mg/kg is administered daily, although some clinicians prefer to start with methylprednisolone 1000 mg daily for 3 days prior to starting prednisone.

Caplacizumab is an anti–von Willebrand factor, single-variable-domain immunoglobulin that inhibits the interaction between ultralarge von Willebrand factor multimers and platelets. Two randomized trials of patients with TTP showed that caplacizumab (10 mg subcutaneously daily) during plasma exchange and for 30 days afterward hastened resolution of the acute TTP episode and reduced the composite endpoint of TTP-related death, recurrent TTP, or a thromboembolic event.[A7,A8] Although caplacizumab can mildly shorten the number of days of plasma exchanges,[27] the very high cost of the drug has raised questions about its cost-effectiveness,[28] and suggests that it is best considered in patients who have neurologic or cardiac symptoms and in whom a very rapid response is needed to prevent impending catastrophic damage to these vital organs.

Additional immunosuppression with rituximab may be beneficial, but this drug does not decrease antibody production for weeks to months after its administration. If rituximab has any benefit in the treatment of TTP, it is probably only to minimize the incidence of late relapses.

Approximately one third to as many as one half of patients relapse after plasmapheresis is discontinued. These patients require a reinitiation of plasma exchange as well as administration of rituximab if this has not already been given.

Major complications of plasmapheresis do occur and are often attributable to the use of a central venous catheter. Hypotension, bacteremia, hemorrhage, and thrombosis are among the most common life-threatening complications of plasmapheresis therapy. Two specific complications deserve emphasis. First, patients taking an angiotensin-converting enzyme (ACE) inhibitor are susceptible to plasmapheresis-induced hypotension. This is due to these drugs' interference with bradykinin catabolism. Second, a patient who develops recurrent thrombocytopenia and a fever several days to a week into treatment may not be having an exacerbation of TTP, but rather may be developing central line–induced sepsis. Therefore, a vigorous investigation for infection should be initiated in patients who appear to be relapsing early.

HEMOLYTIC-UREMIC SYNDROME

DEFINITION

HUS is another cause of microangiopathic hemolytic anemia, and it may be difficult to distinguish from TTP.[29] When acute renal failure is predominant and there are no neurologic symptoms, many clinicians consider the syndrome to be HUS, not TTP. In contrast to TTP, HUS is not caused by a deficiency of ADAMTS13. Instead, HUS is probably caused by damage to endothelial cells leading to thrombosis in small blood vessels and fragmentation of red blood cells as they squeeze past the clots.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

There are three major causes for HUS. The first, and most common, cause of HUS is a Shiga toxin–producing *E. coli* infection. This "typical" form of HUS occurs a few days after a bloody diarrhea syndrome induced by toxigenic *E. coli* (typically serotypes 157:H7 or O104:H4). The Shiga toxin binds to and damages glomerular endothelium, leading to localized thrombus formation, shearing of red cells, and kidney failure.

The next most common type of HUS is in patients who have inherited dysregulation of the alternative complement cascade (Chapter 37), now called complement-mediated (but formerly called atypical) HUS. The best-described genetic mutations cause a deficiency of factor H, which is a complement regulatory protease. HUS-inducing mutations in other components of complement regulation include those found in C3, factor B, CD46, and factor I. In complement-mediated HUS, complement is activated on endothelial cells. Frequently, an upper respiratory tract infection will precede the episode of microangiopathic hemolytic anemia. However, in contrast to typical HUS that is induced by an infection, the infection is only a trigger for complement-mediated HUS in a genetically susceptible host.

The least common variety of HUS is secondary HUS. This is usually caused by drugs or other medical conditions that directly or indirectly promote endothelial cell damage. Several drugs can also induce HUS by directly damaging the endothelial cells. These include calcineurin inhibitors, such as tacrolimus and cyclosporine; sometimes, lowering the dose of these drugs can reverse the microangiopathic hemolytic anemia. Cytotoxic drugs such as mitomycin C, cisplatin, and bleomycin can also induce HUS by directly damaging the endothelial cells. Secondary HUS can also be induced by a variety of autoimmune diseases, cancer, and pregnancy.

TREATMENT AND PREVENTION

Reducing the spread of Shiga toxin–producing *E. coli* is vital because antibiotics and antimotility drugs do not lower the risk for developing HUS symptoms. In contrast to TTP, there is little evidence that plasma exchange is beneficial in these cases. The clinical course and outcome of *E. coli* O104:H4–induced HUS are similar to infections with the more common O157:H7–induced HUS. Aggressive antibiotic therapy appears to be beneficial for reducing seizures and death. However, neither plasmapheresis nor glucocorticoids seem to be helpful for typical or secondary HUS. The infusion of plasma or plasmapheresis is uncertain in the treatment of the forms of HUS that are caused by the dysregulation of complement. Patients with complement-mediated HUS respond better to eculizumab or ravulizumab, which work by inhibiting the terminal complement cascade.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation, which is a pathologic condition that depletes components of the coagulation system, including platelets, is discussed in detail in Chapter 161.

THROMBOCYTOPENIA DURING PREGNANCY

Thrombocytopenia occurs in approximately 10% of pregnant women.[30] It may be due to a normal variant of pregnancy (gestational thrombocytopenia), a pregnancy-specific condition (preeclampsia and HELLP [*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets]) syndrome, or a condition exacerbated by pregnancy (ITP, vasculitis, TTP). Thrombocytopenia occurs in approximately 7 to 10% of pregnancies, and about 75% of these cases are due to gestational thrombocytopenia, 15 to 20% are secondary to hypertensive disorders, 3 to 4% are due to an immune process, and the remaining 1 to 2% are rare constitutional thrombocytopenias, infections, and malignancies. The prognosis and treatment vary tremendously based on the underlying cause.

Gestational Thrombocytopenia

Gestational thrombocytopenia (incidental thrombocytopenia of pregnancy) is a mild, asymptomatic thrombocytopenia that typically occurs late in pregnancy. It occurs predominantly because of hemodilution from expanded plasma volume, although it is possible that there is also a component of increased platelet clearance. Gestational thrombocytopenia is not associated with fetal thrombocytopenia, and this form of maternal thrombocytopenia resolves spontaneously after delivery. Other than thrombocytopenia during previous pregnancies, women with gestational thrombocytopenia have no prior history of a low platelet count. This lack of previous thrombocytopenia helps to distinguish gestational thrombocytopenia from ITP. Additionally, in contrast to other causes of maternal thrombocytopenia, gestational thrombocytopenia does not occur before mid-second trimester, usually does not cause the platelet count to drop below 100,000/μL, and almost never causes a platelet count lower than 75,000/μL. Consequently, deviation from standard obstetric care is not required for a patient with gestational thrombocytopenia.

Preeclampsia

Preeclampsia causes proteinuria and hypertension during the later stages of pregnancy (Chapter 221). A minority of women with preeclampsia progress to have seizures; when this occurs, the syndrome is called *eclampsia*. Approximately 50% of women with preeclampsia have thrombocytopenia. Platelet counts are usually above 100,000/μL, and typically not less than 50,000/μL unless there is another coexisting reason. Some patients have an

unusually severe form of preeclampsia called HELLP syndrome that is associated with a more significant thrombocytopenia, a microangiopathic hemolytic anemia, and markedly elevated liver function tests. Preeclampsia and HELLP syndrome are thought to result from a factor produced within the placenta because these syndromes usually resolve rapidly and spontaneously after delivery. However, the syndrome can also present postpartum. If these syndromes do not resolve spontaneously within 3 days, alternative diagnoses, such as ITP, TTP, or DIC should be considered. Consequently, immediate delivery of the child is recommended, if possible, because the microangiopathic process stops soon thereafter. If no improvement is seen by the third postpartum day and other causes, such as DIC, have been excluded, standard management for TTP, including plasma exchange, is recommended.

Immune Thrombocytopenia

ITP

Although a far less common cause of thrombocytopenia in a pregnant woman than gestational thrombocytopenia or preeclampsia, immune-mediated thrombocytopenia, particularly ITP, is the most common reason for a maternal platelet count less than 50,000/μL. Other than the magnitude of the thrombocytopenia, there is no laboratory test to differentiate ITP from gestational thrombocytopenia. Most patients with ITP or vasculitis during pregnancy have a history of thrombocytopenia before pregnancy. However, pregnancy can exacerbate or even unmask previously unrecognized autoimmune disorders like ITP. The antiplatelet IgG antibodies that cause ITP in the mother can cross the placenta and lead to thrombocytopenia in the fetus. Importantly, the platelet count in the unborn child does not correlate well with the platelet count of the mother, and attempts to sample fetal blood to monitor platelet counts are associated with significant risk.

Because most children born to women with ITP have a platelet count high enough for a successful delivery, the management of ITP focuses on keeping the maternal platelet count acceptable for the mother's safety. A platelet count above 30,000/μL is considered safe in the early stages of pregnancy and for vaginal delivery (although a platelet count above 80,000/μL is recommended for neuraxial anesthesia). A platelet count above 50,000/μL is acceptable for cesarean section. This can be managed by the use of oral glucocorticoids, and if necessary, by the administration of IVIG. Rituximab is not teratogenic but can cause prolonged lymphopenia in both the mother and the neonate. Although there are case reports of using romiplostim during pregnancy, the safety of thrombopoiesis-stimulating agents during pregnancy is not known. Splenectomy is rarely required and has a risk for inducing miscarriage when performed during the first trimester. This operation is also technically difficult during the later stages of pregnancy because of uterine enlargement.

TTP

The diagnosis of TTP during pregnancy can be difficult to make because many of the symptoms are identical to those of preeclampsia. If the symptoms develop during the early stages of pregnancy, when preeclampsia is unlikely, the diagnosis of TTP is more certain. The presence of hyperuricemia, hypoproteinemia, elevated liver transaminases, and direct bilirubin is more consistent with preeclampsia. The absence of elevated liver function abnormalities and the presence of a platelet count less than 20,000/μL or neurologic symptoms support the diagnosis of TTP. A very low (<10%) ADAMTS13 level also supports the diagnosis of TTP, but the results of this test might take some time.

POST-TRANSFUSION PURPURA AND NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

Post-transfusion thrombocytopenia is due to the sensitization to platelet alloantigens, such as PlA1 (HPA-1a).[31] These alloimmune antibodies can cause profound thrombocytopenia approximately a week after a blood transfusion (post-transfusion purpura, or PTP). PTP is often induced by exposure to the small number of platelets that contaminate most red blood cell transfusions. It can be treated with IVIG or by plasma exchange. A similar alloimmune antibody produced by a pregnant woman can cause thrombocytopenia in her fetus (neonatal alloimmune thrombocytopenia, or NAIT). In this condition, the mother herself is not affected, but the neonate might have severe thrombocytopenia and bleeding. Neonatal alloimmune thrombocytopenia is treated with the transfusion of platelets derived from a PlA1-negative donor (most conveniently, the newborn's mother). Corticosteroids and IVIG have also been used.

VASCULITIS

Autoimmune diseases such as systemic lupus erythematosus (Chapter 245), rheumatoid arthritis (Chapter 243), and other forms of vasculitis can also cause thrombocytopenia. This cause is typically an ITP-like process that occurs in patients with a propensity for the development of autoantibodies. The treatment for these patients is immunosuppression, similar to the treatment for other patients with ITP. Some patients with active vasculitis and endothelial inflammation consume circulating platelets by promoting their adhesion to the damaged vessel wall. This creates a clinical picture that is difficult to distinguish from that of TTP without a tissue diagnosis that documents vasculitis or a very low (<10%) ADAMTS13 level. Because of the difficulty of discerning TTP from a flare-up of vasculitis, these patients are often treated with both plasma exchange and immunosuppression.

DILUTIONAL THROMBOCYTOPENIA

Thrombocytopenia does not typically occur after blood loss, possibly in part owing to the release of platelets from the splenic pool. Thrombocytopenia occasionally occurs after a massive hemorrhage. However, this is only when the hemorrhage is severe enough to necessitate the replacement of 1.5 to 2 times the total blood volume, which usually requires the transfusion of at least 15 to 20 units of packed red blood cells over a short period of time. Even in this circumstance, the thrombocytopenia is usually only mild to moderate. Therefore, the clinician should remain vigilant for another cause of the thrombocytopenia (such as DIC resulting from hemorrhage-induced hypotension and shock). When indicated, dilutional thrombocytopenia can be readily corrected with platelet transfusions.

CONGENITAL THROMBOCYTOPENIAS

Lifelong thrombocytopenia can be due to an inherited defect that affects platelet production or survival. Improved access to genetic testing has demonstrated that inherited thrombocytopenia is much more common than previously realized. Mutations in at least 32 genes can cause inherited thrombocytopenia. These disorders can be autosomal dominant (May-Hegglin anomaly and Sebastian syndrome), autosomal recessive (Bernard-Soulier disease, Fanconi anemia, gray platelet syndrome, thrombocytopenia with absent radius syndrome, and Paris Trousseau), or X-linked (Wiskott-Aldrich syndrome, GATA1-related, and FLNA-related). Many of these disorders are associated with other abnormalities in addition to thrombocytopenia such as kidney failure, cataracts, deafness, and predisposition to bone marrow failure or hematologic malignancies. A congenital cause of thrombocytopenia should be suspected in a patient who has long-standing moderate thrombocytopenia that was presumed to be treatment-refractory ITP. However, the majority of patients with chronic borderline thrombocytopenia and platelet counts greater than 100,000/μL continue to have stable platelet counts a decade later,[32] and many are likely to be outliers at the lower range of physiologic platelet counts.

159 VON WILLEBRAND DISEASE AND HEMORRHAGIC ABNORMALITIES OF PLATELET AND VASCULAR FUNCTION

JORGE DI PAOLA AND JAMES S. O'DONNELL

VON WILLEBRAND DISEASE

DEFINITION AND EPIDEMIOLOGY

Von Willebrand disease, which is the most common inherited bleeding disorder, is caused by quantitative or qualitative reductions in plasma von Willebrand factor (VWF). Significant bleeding symptoms due to reduced levels of von Willebrand factor are present in approximately 1 in 1000 individuals, with a prevalence that appears to be relatively consistent across different races and ethnicities. Importantly, however, population studies have demonstrated that not all people with reduced plasma levels of von Willebrand factor have clinically relevant bleeding, and the true prevalence of asymptomatic von Willebrand disease is less certain.

PATHOBIOLOGY

The human *VWF* gene consists of 52 exons and spans 178 kb on chromosome 12. Von Willebrand factor is a large multimeric plasma glycoprotein that plays two essential roles in normal hemostasis. First, it mediates platelet adhesion to exposed subendothelial tissues at sites of vascular injury. Second, von Willebrand factor acts as a carrier molecule for procoagulant factor VIII, thereby protecting it from premature proteolytic degradation and clearance. Von Willebrand factor and factor VIII circulate together in a noncovalent complex in normal plasma. In vivo, expression of von Willebrand factor is limited to endothelial cells and megakaryocytes. Von Willebrand factor that is synthesized within megakaryocytes is subsequently stored within the α-granules of their platelet progeny. This platelet von Willebrand factor accounts for 10 to 20% of the total amount that is present in normal platelet-rich plasma. In contrast, von Willebrand factor that is synthesized within endothelial cells is either released directly into the plasma through a constitutive secretory pathway or stored in dedicated organelles known as Weibel-Palade bodies. Consequently, under normal steady-state conditions, plasma von Willebrand factor is derived chiefly from endothelial cells. Regulated secretion of von Willebrand factor from its stores within Weibel-Palade bodies can be triggered by a variety of different secretagogues including histamine, thrombin, and desmopressin (DDAVP [1-desamino-8-D-arginine vasopressin]). Similarly, von Willebrand factor is secreted from α-granules following platelet activation.

Within endothelial cells, von Willebrand factor undergoes complex post-translational modification prior to its secretion into the plasma. In the endoplasmic reticulum, individual monomers of von Willebrand factor are assembled into dimers through the formation of C-terminal disulphide bonds. Subsequently, von Willebrand factor dimers form high-molecular-weight multimers in the Golgi after another round of N-terminal disulphide bond formation. As a result, von Willebrand factor circulates in the form of heterogeneous multimers that contain a variable number of subunits, ranging from a minimum of 2 to a maximum of 100. The largest multimers have molecular weights in excess of 20,000 Kd. Multimeric composition is a critical determinant of von Willebrand factor's functional activity. High-molecular-weight multimers bind both collagen and platelets with higher affinities, and they are more efficient in inducing platelet aggregation under high-shear conditions. In normal plasma, the multimeric composition of circulating von Willebrand factor is tightly regulated by a specific cleaving metalloprotease termed ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13).[1]

To facilitate platelet-plug formation at sites of vascular injury, von Willebrand factor also must be able to bind to exposed subendothelial collagen. Specific domains of von Willebrand factor interact with different types of collagen. For example, the A3 domain binds to collagen types I and III, whereas the principal binding site for types IV and VI collagen is located within the A1 domain.

In the normal population, plasma levels of von Willebrand factor typically vary between 50 to 150 IU/dL, and von Willebrand disease is classified into three distinct subtypes (Table 159-1). Type 1 von Willebrand disease is characterized by a partial quantitative deficiency in plasma levels of von Willebrand factor (<50 IU/dL) and accounts for the majority (about 75%) of cases. Type 2 von Willebrand disease includes patients who have qualitative disorders that impair one or more aspects of von Willebrand factor's normal functional activity. In these patients, the total amount of von Willebrand factor antigen (VWF:Ag) in the plasma may be normal or slightly reduced. In contrast, however, functional assays of von Willebrand factor are significantly reduced. Type 2 von Willebrand disease accounts for about 25% of cases and is further subdivided (type 2A, 2B, 2M, and 2N respectively) based upon the nature of the underlying qualitative defect of von Willebrand factor (Table 159-1). Type 3 von Willebrand disease is a rare (1 per million; about 1% of cases) and severe bleeding disorder characterized by near-complete deficiency in plasma von Willebrand factor.[2]

CLINICAL MANIFESTATIONS

Bleeding symptoms in patients with von Willebrand disease vary depending upon the residual levels of plasma VWF activity levels and the disease subtype. Patients typically present with mucocutaneous bleeding including epistaxis, gum bleeding, easy bruising, and bleeding from minor wounds. Recurrent gastrointestinal bleeding is a common presentation, particularly in patients with types 2 or 3 von Willebrand disease.[3]

Although von Willebrand disease is inherited in an autosomal manner, clinical disease is more prevalent in females because they face greater hemostatic challenges. For example, heavy menstrual bleeding occurs in up to 80% of women with von Willebrand disease and is often associated with iron deficiency (Chapter 145). Furthermore, undiagnosed von Willebrand disease is common (about 15% of cases) in women who present for investigation of

TABLE 159-1 CLASSIFICATION AND DIAGNOSIS OF VON WILLEBRAND DISEASE

TYPE VWD	DESCRIPTION	FVIII	RCo	VWF	RCo:VWF RATIO	MULTIMERS	SPECIAL TESTING
Normal range		50-150%	50-200%	50-200%	>0.7	Normal	
Type 1	Quantitative deficiency	↓ or N	<30%	<30%	>0.7	Normal distribution; decreased quantity	VWF propeptide:VWF ratio >0.6 in type 1 C; exon 28 DNA testing
Type 2A	Qualitative VWF defect	↓ or N	↓	N to ↓	<0.7	Loss of HMW forms	Exon 28 DNA testing
Type 2B	Qualitative gain of function; depletes HMW multimers	↓ or N	↓	N to ↓	<0.7	Loss of HMW forms	↑ RIPA low doses; exon 28 DNA testing
Type 2M	Qualitative defect	↓ or N	↓	N to ↓	<0.7	Normal	↓ CB
Type 2N	Qualitative defect only in FVIII binding	↓↓	N	N	>0.7	Normal	↓ VWF:FVIII binding study
Type 3	Near absence of VWF	↓↓	<3%	<3%	NA	None	
"Low VWF"	Borderline values	N	30-50%	30-50%	>0.7	Normal	

Typical or classical laboratory findings are described for each diagnosis. Expert interpretation is often required for patients without classical findings.
CB = collagen binding activity for VWF function; FVIII = factor VIII activity; HMW = high-molecular-weight; N = normal; Plt-VWD = platelet-type von Willebrand disease; RCo = ristocetin cofactor activity for VWF function; RIPA = ristocetin-induced platelet aggregation; VWF = von Willebrand factor antigen; ↑ = increased; ↓ = decreased value, with more arrows reflecting greater extent of decrease.
Data from Leebeek FWG, Eikenboom JCJ. Von Willebrand's disease. *N Engl J Med.* 2016;375:2067-80.

ABSTRACT

Von Willebrand disease, which is the most common inherited bleeding disorder, affects about 0.1% the population. A careful bleeding history can guide specialized testing to determine the specific type of von Willebrand disease. Treatments include desmopressin, which stimulates release of the patient's own von Willebrand factor, and infusion of von Willebrand factor concentrates. Tranexamic acid is useful for acute bleeding episodes. Acquired von Willebrand disease syndrome is often associated with paraproteinemias and hematologic malignancies, and its treatment focuses on ameliorating the precipitating condition. Functional platelet defects can be congenital or acquired, usually related to drugs that are used therapeutically as antiplatelet agents. Uncommon primary vascular disorders that lead to bleeding, including hereditary hemorrhagic telangiectasia and Ehlers-Danlos syndrome, currently have no specific effective treatment.

von Willebrand disease
Bernard-Soulier syndrome
Glanzmann thrombasthenia
platelet function disorders
delta storage pool disease

unexplained heavy menstrual bleeding. Significant bleeding can also occur in von Willebrand disease patients after hemostatic challenges, including dental extractions or surgical procedures.[4] Although plasma levels of von Willebrand factor progressively increase during pregnancy, women with von Willebrand disease have increased rates of both primary and secondary postpartum hemorrhage. Patients with type 3 von Willebrand disease have markedly reduced plasma factor VIII levels and present with recurrent spontaneous bleeding into joints. As in patients with severe hemophilia (Chapter 160), they can ultimately develop progressive arthropathy.

DIAGNOSIS

Clinical Assessment

A complete medical history and clinical examination are important in patients who undergo investigation for a possible bleeding tendency (Fig. 159-1). This history should include any family bleeding tendency or consanguinity, as well as a comprehensive list of current medications and health supplements. Clinical examination may demonstrate evidence of bleeding such as petechiae, ecchymosis, or hematomas. Signs of collagen vascular disorders (including skin laxity, joint hypermobility, joint dislocations, delayed wound healing) should be investigated. Any signs suggesting other inherited or acquired causes of bleeding disorders (e.g., senile purpura hereditary hemorrhagic telangiectasia, Cushing syndrome [Chapter 208], scurvy [Chapter 199], liver disease [Chapter 161], amyloidosis [Chapter 174], hypothyroidism [Chapter 207], paraproteinemia [Chapter 173], and myeloproliferative disorders) should be noted.

In clinical practice, the diagnosis of von Willebrand disease is based upon a bleeding phenotype combined with abnormal laboratory testing, sometimes aided by a family history. Investigation begins with an objective assessment of bleeding history (Fig. 159-1), which is best achieved using a standardized bleeding assessment tool (Table 159-2) to evaluate bleeding symptoms across different domains. Normal bleeding scores are less than 4 in males and less than 6 in females, so laboratory testing for von Willebrand disease and other bleeding disorders is indicated in males who score 4 or more or females who score 6 or more.[5]

Laboratory Evaluation

The prothrombin time (PT) and activated partial thromboplastin time (APTT) may be normal in patients with von Willebrand disease. Initial laboratory testing should also include measurement of plasma levels of von Willebrand factor antigen.[6] In view of the variability in plasma levels of von Willebrand factor, assays should be repeated on two separate occasions several weeks apart. Undetectable plasma levels of von Willebrand factor antigen (typically <3 IU/dL) are consistent with a diagnosis of type 3 von Willebrand disease, whereas partial quantitative deficiency (levels of 3 to 50 IU/dL) are diagnostic of type 1 von Willebrand disease (Fig. 159-1).[7] Since von Willebrand disease can be quantitative or qualitative in nature, laboratory testing must also include assessment of the various functional activities of von Willebrand factor (interactions with platelet GpIbα, collagen, and factor VIII). The von Willebrand factor ristocetin cofactor activity assay traditionally has been the gold standard test of von Willebrand factor function, but platelet-dependent von Willebrand factor activity is better measured by assays of von Willebrand factor glycoprotein 1b recombinant and von Willebrand factor glycoprotein 1b mutant. Commercial assays (typically containing types I and/or III collagen) can measure the binding of von Willebrand factor to collagen. Testing for the binding of von Willebrand factor to collagen types IV and VI has mainly been limited to research laboratories.

TABLE 159-2 INTERNATIONAL SOCIETY ON THROMBOSIS AND HAEMOSTASIS—SCIENTIFIC AND STANDARDIZATION COMMITTEE BLEEDING ASSESSMENT TOOL

	SCORE				
SYMPTOMS (UP TO THE TIME OF DIAGNOSIS)	**0***	**1***	**2**	**3**	**4**
Epistaxis	No/trivial	≥5/year or >10 minutes	Consultation only†	Packing or cauterization or antifibrinolytic	Blood transfusion or replacement therapy (use of hemostatic blood components and recombinant factor VIIa) or desmopressin
Cutaneous	No/trivial	For bruises 5 or more (>1 cm) in exposed areas	Consultation only†	Extensive	Spontaneous hematoma requiring blood transfusion
Bleeding from minor wounds	No/trivial	≥5/year or >10 minutes	Consultation only†	Surgical hemostasis	Blood transfusion, replacement therapy, or desmopressin
Oral cavity	No/trivial	Present	Consultation only†	Surgical hemostasis or antifibrinolytic	Blood transfusion, replacement therapy, or desmopressin
Gastrointestinal bleeding	No/trivial	Present and not associated with ulcer, portal hypertension, hemorrhoids, or angiodysplasia	Consultation only†	Surgical hemostasis or antifibrinolytic	Blood transfusion, replacement therapy, or desmopressin
Hematuria	No/trivial	Macroscopic	Consultation only†	Surgical hemostasis or iron therapy	Blood transfusion, replacement therapy, or desmopressin
Tooth extraction	No/trivial or never performed	Reported in ≤25% of all procedures, no intervention‡	Reported in ≥25% of all procedures, no intervention‡	Resuturing or packing	Blood transfusion, replacement therapy, or desmopressin
Surgery	No/trivial or never performed	Reported in ≤25% of all procedures, no intervention‡	Reported in ≥25% of all procedures, no intervention‡	Resuturing or packing	Blood transfusion, replacement therapy, or desmopressin
Menorrhagia	No/trivial	Consultation only† or Changing pads more frequently than every 2 hours or Clot and flooding	Time off work/school >2/year or Requiring antifibrinolytics or hormonal or iron therapy	Requiring combined treatment with antifibronlytics and hormonal therapy or present since menarche and >12 months	Acute menorrhagia requiring hospital admission and emergency treatment, requiring blood transfusion, replacement therapy, or desmopressin; or requiring dilatation and curettage or endometrial ablation or hysterectomy
Postpartum hemorrhage	No/trivial or no deliveries	Consultation only† or use of syntocin or lochia >6 weeks	Iron therapy or antifibrinolytics	Requiring blood transfusion, replacement therapy, or desmopressin; or requiring examination under anesthesia and/or the use of uterine balloon/package to tamponade the uterus	Any procedure requiring critical care or surgical intervention (e.g., hysterectomy, internal iliac artery legation, uterine artery embolization, uterine brace sutures)
Muscle hematomas	Never	Post-trauma, no therapy	Spontaneous, no therapy	Spontaneous or traumatic, requiring desmopressin or replacement therapy	Spontaneous or traumatic, requiring surgical intervention or blood transfusion
Hemarthrosis	Never	Post-trauma, no therapy	Spontaneous, no therapy	Spontaneous or traumatic, requiring desmopressin or replacement therapy	Spontaneous or traumatic, requiring surgical intervention or blood transfusion
Central nervous system bleeding	Never			Subdural, any intervention	Intracerebral, any intervention
Other bleeding§	No/trivial	Present	Consultation only†	Surgical hemostasis or antifibrinolytics	Blood transfusion, replacement therapy, or desmopressin

SCORE

*Distinction between 0 and 1 is of critical importance. Score 1 means that the symptom is judged as present in the patient's history by the interviewer but does not qualify for a score 2 or more.

†Consultation only: the patient sought medical evaluation and was either referred to a specialist or offered detailed laboratory investigation.

‡Example: one extraction/surgery resulting in bleeding (100%): the score to be assigned is 2; two extractions/surgeries, one resulting in bleeding (50%): the score to be assigned is 2; three extractions/surgeries, one resulting in bleeding (33%): the score to be assigned is 2; four extractions/surgeries, one resulting in bleeding (25%): the score to be assigned is 1.

§Includes umbilical stump bleeding, cephalohematoma, cheek hematoma caused by sucking during breast/bottle feeding, conjunctival hemorrhage or excessive bleeding following circumcision or venipuncture. Their presence in infancy requires detailed investigation independently from the overall score.

By definition, patients with type 2 von Willebrand disease have a qualitative defect in von Willebrand factor. Consequently, their plasma antigen levels of von Willebrand factor are typically normal or only mildly reduced. However, a marked reduction in one or more aspects of the functional activity of von Willebrand factor results in an activity to antigen ratio below 0.7. In patients confirmed to have type 2 von Willebrand disease, the next step is to subclassify the abnormality based upon the specific nature of their qualitative defect using additional laboratory assays, including von Willebrand factor multimer analysis and the ristocetin-induced platelet aggregation assays (Fig. 159-1). Type 2A von Willebrand disease includes qualitative variants with reduced platelet

adhesion and loss of high-molecular-weight multimers. In contrast, type 2M von Willebrand disease incorporates variants that have reduced platelet adhesion not caused by loss of high molecular multimers. Type 2B von Willebrand disease involves variants in which gain-of-function mutations lead to increased affinity for platelet GpIbα. Consequently, patients with type 2B von Willebrand disease can have fluctuating thrombocytopenia. Finally, type 2N von Willebrand disease is characterized by qualitative variants with decreased affinity for factor VIII.

Guidelines also recommend genetic testing for the diagnosis and subclassification of patients with type 2 von Willebrand disease, especially to distinguish type 2N from mild hemophilia A. Molecular analysis may also be useful for counseling and prenatal diagnosis in families with type 3 von Willebrand disease. In contrast, the utility of genetic testing in patients with type 1 von Willebrand disease remains unclear, because a variety of different sequence variants have been described spanning the *VWF* gene (https://databases.lovd.nl/shared/genes/VWF).

TREATMENT

Where possible, patients with von Willebrand disease should be managed in comprehensive referral centers with a multidisciplinary team that is experienced in treating patients who have bleeding disorders.[8] For elective procedures or bleeding complications, individualized treatment plans should be developed under expert oversight based on both patient- and procedure-related factors (Table 159-3). Patient-related factors to consider include the type of von Willebrand disease and the nadir levels of plasma von Willebrand factor antigen, von Willebrand factor activity, and factor VIII. Plasma levels of von Willebrand factor and factor VIII increase with aging in many patients with type 1 von Willebrand disease and may sometimes correct into the normal range, but even such levels may not result in a complete correction of the bleeding phenotype. Although the Bleeding Assessment Tool score can provide objective data on previous bleeding, it is less useful in patients who have had limited prior exposure to hemostatic challenges.

Tranexamic Acid

Tranexamic acid, which is a fibrinolytic inhibitor that is widely used in the treatment of von Willebrand disease, can be administered orally (typical dose 15 to 25 mg/kg three times daily) or intravenously (typical dose 15 mg/kg three times daily).[9] Even in high-risk populations (e.g., trauma, postpartum hemorrhage, major orthopedic surgery), tranexamic acid is associated with minimal thrombotic risk. However, tranexamic acid is usually avoided in patients with significant hematuria because it has been associated with clot retention and urinary obstruction.

TABLE 159-3 VON WILLEBRAND FACTOR REPLACEMENT GUIDELINES FOR BLEEDING/PROCEDURES

PROCEDURES/BLEEDING EVENTS DURATION	DOSING RECOMMENDATIONS
Major surgery: 7-14 days Cardiothoracic Cesarean section Craniotomy/Spinal cord Abdominal Prostatectomy	Initial dose: 40-60 RCo units/kg Maintenance doses: 20-40 RCo units/kg every 8-24 hr Monitor: FVIII and RCo trough and peak daily Targets: troughs >50%; peaks <200% RCo, <250% FVIII In responsive patients; may use desmopressin later in treatment
Minor surgery: 1-5 days Biopsies Complex dental extractions Gingival surgery Indwelling catheter placement Laparoscopies	Initial dose: 30-60 RCo units/kg Maintenance doses: 20-40 RCo units/kg every 12-48 hr Monitor: RCo and FVIII Targets: troughs >50%; peaks <200% RCo, <250% FVIII In responsive patients; may use desmopressin later in treatment Antifibrinolytic agent for 7-10 days is useful adjunct for dental procedures
Other procedures: one dose Cardiac catheterization Endoscopy with or without biopsies Liver biopsy Lacerations Simple dental extractions	Dose: 20-40 RCo units/kg Rare need for subsequent doses with multiple endoscopic biopsies Monitor: typically not done/required Desmopressin may suffice in very responsive patients Antifibrinolytic agent for 7-10 days useful adjunct for dental procedures

FVIII = factor VIII; RCo = ristocetin cofactor activity for von Willebrand factor function.

Von Willebrand disease and hemorrhagic abnormalities of platelet and vascular function. In: Goldman L, Schafer AI. *Goldman-Cecil Medicine*. 26th ed. Elsevier; Philadelphia: 2020.

DDAVP

DDAVP, which is a synthetic analog of L-arginine vasopressin, induces secretion of von Willebrand factor from Weibel-Palade body stores within endothelial cells and thereby can be used to elevate plasma levels of von Willebrand factor transiently. It can be administered intravenously (typical dose 0.3 μg/kg in 100 mL of normal saline infused over 20 minutes, maximum dose 25 to 30 μg) or can be given intranasally (300 μg total dose or 150 μg per nostril for persons >50 kg body weight). DDAVP is widely used in the treatment of type 1 von Willebrand disease and may also be useful in some patients with types 2A and 2M von Willebrand disease. However, it is generally avoided in type 2B von Willebrand disease, in which it can trigger significant thrombocytopenia, and it is not useful in patients with type 3 von Willebrand disease. Importantly, the increases in plasma levels of von Willebrand factor following DDAVP treatment vary significantly among individual patients with von Willebrand disease, so a DDAVP trial should be performed in each patient to define their individual response. Plasma levels of von Willebrand factor and factor VIII should be measured at 30 minutes and 4 hours post-DDAVP to assess both peak levels and the duration of the response. For acute bleeding or surgical procedures, DDAVP can be repeated every 12 to 24 hours, but tachyphylaxis can diminish the rise in the von Willebrand factor level following repeated treatments. DDAVP can cause fluid retention with secondary hyponatremia and seizures, so fluid restriction (1500 mL over 24 hours) is commonly instituted following DDAVP therapy. Plasma sodium levels should also be measured prior to any repeat dosing. DDAVP is generally avoided in elderly patients who have cardiovascular risk factors.

Plasma-Derived Concentrates of von Willebrand Factor

A number of different plasma-derived concentrates containing von Willebrand factor are licensed for use in patients whose von Willebrand disease fails to respond to DDAVP or who have contraindications to it.[10] In normal individuals, von Willebrand factor has a plasma half-life of approximately 12 to 16 hours, so treatment with DDAVP or plasma-derived von Willebrand factor concentrates can generally be administered once daily to prevent perioperative bleeding or to treat patients who present with acute bleeding. Current guidelines recommend that plasma activity levels of von Willebrand factor and factor VIII should be maintained at ≥50 IU/dL for at least 3 days after surgical procedures. Repeated infusions of factor VIII–containing von Willebrand factor concentrates have been associated with elevated levels of plasma factor VIII procoagulant activity and rare cases of thrombosis.

Recombinant von Willebrand Factor

Recombinant human von Willebrand factor (rVWF) concentrate, which differs from plasma-derived von Willebrand factor concentrates in that it is enriched in high-molecular-weight multimers and does not contain significant amounts of factor VIII, is highly effective.[A1] However, co-infusion of recombinant factor VIII may be necessary with the first dose of recombinant von Willebrand factor to ensure immediate hemostatic factor VIII levels are achieved. In the absence of concurrent recombinant factor VIII infusion, 6 hours may be required following the infusion of recombinant von Willebrand factor before plasma factor VIII procoagulant activity levels rise to above 40 IU/dL in patients with type 3 von Willebrand disease.

Platelet Transfusion

About 10 to 20% of von Willebrand factor is stored within platelet α-granules. Anecdotal reports suggest that platelet transfusion may be a useful adjunctive therapy in managing resistant bleeding in patients who have von Willebrand disease.

Von Willebrand Disease Management Strategies

Routine prophylaxis with von Willebrand factor usually is not required, except in patients who have severe disease or recurrent gastrointestinal bleeding.[11] Episodic treatment is key at the time of bleeding and prior to procedures that typically precipitate bleeding (Fig. 159-2). Prior to surgery, DDAVP or a von Willebrand factor concentrate should be infused.[12] Plasma von Willebrand factor activity and factor VIII procoagulant activity levels should then be assessed to ensure hemostatic levels have been achieved (≥ 50 IU/dL for minor procedures and ≈100 IU/dL for major surgery; Table 159-2). In addition, tranexamic acid should be commenced preoperatively and continued during the postoperative period. Following major surgery, trough levels of von Willebrand factor activity and factor VIII procoagulant activity levels should be repeated on a daily basis, with additional DDAVP or von Willebrand factor concentrate administered daily to maintain trough levels ≥50 IU/dL for at least 5 to 10 days (Table 159-2).[13,14]

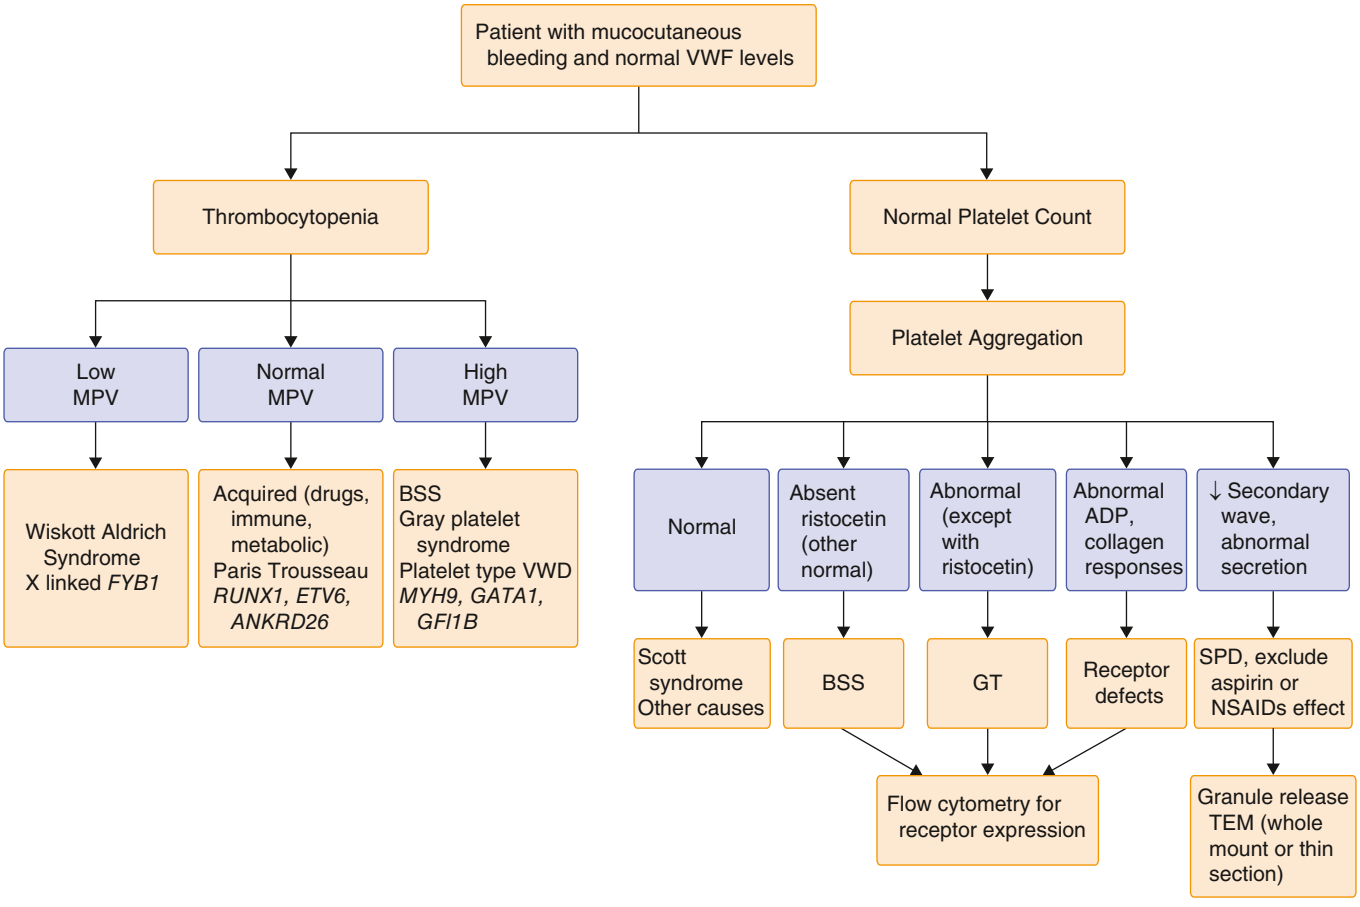

FIGURE 159-2. Platelet disorder diagnostic algorithm. ADP = adenosine diphosphate; BSS = Bernard-Soulier syndrome; GT = Glanzmann thrombasthenia; MPV = mean platelet volume; NSAIDs = nonsteroidal anti-inflammatory drugs; SPD = storage pool defect; TEM = transmission electron microscopy; VWD = von Willebrand disease.

PROGNOSIS

Some patients with type 1 and type 2 von Willebrand disease require specific treatment only around times of surgery, injury, or childbirth. However, other patients with severe type 1 and type 2 von Willebrand disease have recurrent lifelong bleeding issues that significantly impair their quality of life. Recurrent gastrointestinal bleeding often worsens with age, particularly in patients with type 2 VWD. Spontaneous joint bleeds can lead to progressive arthropathy in patients with type 3 VWD.

ACQUIRED VON WILLEBRAND SYNDROME

Acquired von Willebrand syndrome is an uncommon bleeding disorder that results from reduced plasma activity of von Willebrand factor in individuals who have no prior personal or family history of von Willebrand disease.[15] Acquired von Willebrand syndrome often occurs in association with underlying conditions, with 30 to 50% being associated with underlying lymphoproliferative disorders such as monoclonal gammopathy of undetermined significance (Chapter 173), multiple myeloma (Chapter 173), Waldenström macroglobulinemia (Chapter 173), non-Hodgkin lymphoma (Chapter 171), chronic lymphocytic leukemia (Chapter 168), and hairy cell leukemia (Chapter 168). Acquired von Willebrand syndrome has also been associated with a variety of other myeloproliferative disorders, autoimmune disorders, and malignancies. Mechanisms implicated in the pathogenesis of acquired von Willebrand syndrome include anti–von Willebrand factor antibodies that are associated with markedly enhanced clearance of von Willebrand factor. Cardiovascular disorders associated with pathological shear stress (e.g., aortic stenosis, extracorporeal membrane oxygenation, and left ventricular assist devices) can lead to loss of high-molecular-weight multimers due to enhanced proteolysis of von Willebrand factor by ADAMTS13.

TREATMENT

Management should focus primarily on treating any underlying conditions. Acute bleeding episodes can be difficult to manage and may be refractory to standard treatment options for von Willebrand disease. For example, although DDAVP and infusions of von Willebrand factor concentrate may cause an initial increase in levels of von Willebrand factor and factor VIII, these levels typically decline rapidly, so frequent monitoring is essential. Some patients with paraproteins may respond to intravenous immunoglobulin (IVIg), although responses in levels of von Willebrand factor and factor VIII may be delayed for several days. A combination of intravenous immunoglobulin and von Willebrand factor concentrate under expert supervision may be useful in managing elective procedures in some patients. Other treatment options include tranexamic acid, plasmapheresis, and recombinant factor VIIa.[16] Prognosis is generally determined by the prognosis of the underlying cause.

QUALITATIVE PLATELET DISORDERS

Inherited Platelet Bleeding Disorders

EPIDEMIOLOGY AND PATHOLOGY

Inherited disorders of platelet function are rare. These disorders include platelet receptor defects, platelet storage pool disorders, and a variety of other defects.

Each day, bone marrow megakaryocytes generate about 10^{11} anucleate platelets to maintain a platelet count of 150,000 to 450,000/μL. Platelets circulate in plasma and activate at sites of vascular injury to form a platelet clot. When the subendothelium is exposed due to injury, platelets bind to collagen, von Willebrand factor, and other extracellular matrix proteins via the von Willebrand factor receptor glycoprotein 1b/IX/V complex and collagen receptors such as $\alpha_2\beta_1$ and glycoprotein VI. This adhesion process triggers intracellular signaling events that lead to the activation of the fibrinogen receptor GPIIbIIIa, which is also known as integrin $\alpha_{2b}\beta_3$. The binding of fibrinogen leads to further signaling that causes platelets to change shape, granules to be released, and eventually the flipping of the membrane phospholipid layer to expose phosphatidyl serine, which provides docking sites for coagulation factors and ultimately supports the formation of a fibrin clot. In every step in the process, inherited platelet defects can compromise the performance and efficiency of these functions, thereby potentially leading to clinical bleeding.

CLINICAL MANIFESTATIONS

As with von Willebrand disease, bleeding associated with platelet disorders is often mucocutaneous (petechiae, purpura, ecchymoses, and hematomas), whereas joint or deep muscle bleeds are relatively uncommon. Affected women can have excessive menstrual bleeding (menorrhagia) and postpartum hemorrhage. Platelet dysfunction should also be suspected in the presence of increased bleeding following dental extraction, tonsillectomy, or other surgical procedures.

DIAGNOSIS

The bleeding assessment tool score used for von Willebrand disease is also useful in identifying patients with platelet function disorders, with a 99% probability if von Willebrand disease is excluded. A careful history may provide clues about whether the bleeding disorder is acquired or congenital, because platelet dysfunction may be related to other systemic disorders.

If studies for a plasma coagulation factor deficiency and von Willebrand disease are negative, functional platelet studies that should be performed at specialized centers include light transmission aggregometry, flow cytometry, and assays of platelet granule content and release (Fig. 159-2). Gene panels can test for inherited thrombocytopenias and disorders of platelet function in patients who have normal platelet counts, although the interpretation of such panels[17] can be challenging and they can miss large structural variants and deep intronic regions.[18]

SPECIFIC QUALITATIVE PLATELET DISORDERS

Platelet Receptor Defects

The most commonly diagnosed receptor defects are Bernard-Soulier syndrome and Glanzmann thrombasthenia. Other platelet receptor defects associated with clinical bleeding include defects in the thromboxane, adenosine diphosphate, and collagen receptors, but these deficiencies are extremely rare and described in only a few families or cases.[19]

Bernard-Soulier Syndrome

Bernard-Soulier syndrome is an autosomal recessive disorder characterized by macrothrombocytopenia and caused by deficiency or dysfunction of GP1b/IX/V complex due to mutations in *GP1BA*, *GP1BB*, and *GP9*. In this disorder, platelets respond poorly to ristocetin in platelet aggregation studies but respond normally to other commonly used agonists, such as adenosine diphosphate (ADP), arachidonic acid, collagen, and epinephrine. The clinical presentation can be variable, but mucocutaneous bleeding is typically present. Flow cytometry usually confirms the absence of the receptor on the platelet surface, although some forms can present with a hypofunctional receptor expressed at lower levels than normal. The monoallelic form is much less severe and is associated with large platelets and somewhat low platelet counts; it can be diagnosed only by flow cytometry or genetic studies.

Glanzmann Thrombasthenia

Glanzmann thrombasthenia, which is also an autosomal recessive disorder of platelet aggregation, is caused by mutations in the genes *ITGA2B* and *ITGB3* that encode for the fibrinogen receptor GPIIbIIIa. Although the clinical presentation is also variable, bleeding tends to be severe since childhood. Patients exhibit normal platelet counts and normal platelet structure. Platelet light transmission aggregometry shows a normal response to ristocetin because the GPIb/IX/V complex is preserved, but responses to ADP, collagen, epinephrine, and arachidonic acid are very depressed or absent. The diagnosis of Glanzmann thrombasthenia can be confirmed by flow cytometry for the GPIIbIIIa receptor density and genetic testing. The complete absence of the receptor is defined as type 1, whereas moderate decreases to 10 to 20% of normal are defined as type 2.

Platelet Granule Defects

Disorders of platelet granules are rare. The most commonly diagnosed platelet function disorder is the platelet dense granule storage pool deficiency, which is usually diagnosed by a combination of mild bleeding, abnormal platelet aggregation (lack of secondary wave), and a decrease in the number of dense granules assessed by wet mount or thin section transmission electron microscopy. Bleeding is usually mild but can be more severe. In the autosomal recessive Hermansky-Pudlak syndrome, up to 10 different genes can have mutations that cause different subtypes. In this syndrome, which is accompanied by ocular albinism, platelets are normal in number and size, but the number of dense granules is severely decreased or even absent. Some patients with specific subtypes also develop severe pulmonary fibrosis, ophthalmologic complications, granulomatous colitis, and immune defects.

TABLE 159-4 SOME COMMON AGENTS CAUSING ACQUIRED PLATELET DYSFUNCTION

TYPE OF AGENT	EXAMPLES
Antiplatelet agents	Aspirin, clopidogrel, prasugrel, ticagrelor, ticlopidine, abciximab, eptifibatide, tirofiban
Nonsteroidal anti-inflammatory agents	Ibuprofen, naproxen, indomethacin diclofenac, tolmetin, piroxicam
Selective serotonin reuptake inhibitors	Fluoxetine, paroxetine, sertraline
Plasma expanders	Dextrans, hydroxyethyl starch
Antihistamines	Chlorpheniramine, diphenhydramine
Foods and supplements	Vitamin E, fish oil, omega-3-fatty acids, alcohol, garlic, Chinese black tree fungus, ginger, cumin, turmeric, onion, cloves
Phosphodiesterase inhibitors	Cilostazol, dipyridamole, caffeine, theophylline, aminophylline, sildenafil

Data from Casari C, Bergmeier W. Acquired platelet disorders. *Thromb Res*. 2016;141(Suppl 2):S73-S75.

In Chédiak-Higashi syndrome (Chapters 153 and 231), a disorder of platelet dense granules is associated with oculocutaneous albinism, neutropenia, and severe immune deficiency. Patients also have large neutrophilic cytoplasmic inclusions and can develop life-threatening lymphohistiocytosis.

The autosomal recessive gray platelet syndrome is characterized by a complete absence of α-granules. This syndrome is caused by recessive loss of function mutations in *NBEAL2*. The platelets appear gray on a peripheral smear, and the diagnosis is confirmed by transmission electron microscopy. Although the bleeding diathesis is usually mild to moderate, the syndrome can be associated with splenomegaly and bone marrow fibrosis later in life. Other rare syndromes associated with abnormal α-granules are associated with mutations in *FLI1*, *GFI1B*, *STIM1*, and *GATA1*.

Other Inherited Platelet Function Disorders

Over 75 genes have been associated with inherited platelet disorders. These disorders are typically diagnosed on gene panels. Some of these disorders (e.g., mutations in *RUNX1*, *ETV6*, and *ANKRD26*) are associated with an increased risk of malignancies.

Acquired Platelet Dysfunction

The most common cause of acquired platelet dysfunction[20] is antiplatelet medications (Chapter 70), including aspirin, the thienopyridines (clopidogrel, prasugrel), nonthienopyridines P2Y12 inhibitors (ticagrelor, cangrelor), and the GPIIbIIIa inhibitors (tirofiban, eptifibatide, and abciximab). However, other drugs (Table 159-4) and dietary supplements can inhibit platelet function and result in easy bruising or bleeding.

Hematologic disorders such as paraproteinemias (Chapter 173), myeloproliferative neoplasms, and myelodysplastic syndrome (Chapter 167) can cause functional platelet disorders, sometimes accompanied by thrombocytopenia. Patients with end-stage renal disease (Chapter 116) or with liver failure (Chapter 140) often develop platelet dysfunction. Immune thrombocytopenic purpura also can be associated with platelet dysfunction owing to having antibodies against specific platelet receptors. Transient platelet dysfunction is seen during cardiac surgery with cardiopulmonary bypass.

TREATMENT

In most patients with congenital or acquired platelet disorders, transfusion of donor platelets is the recommended treatment. Unfortunately, patients who receive multiple platelet transfusions can become resistant because of immunity to platelet-specific or HLA-related antigens. In Glazmann thrombasthenia, alloimmunization can lead to a refractoriness to platelet transfusions; as a result, many experts prefer activated recombinant factor VIIa as the first line of treatment and reserve platelet transfusions for life-threatening bleeding.

DDAVP is effective in treating uremic bleeding and platelet dysfunction and may provide some benefit when individuals with a storage pool defect and Bernard-Soulier syndrome develop mild to moderate bleeding. Administration of DDAVP may cause fluid retention and hyponatremia, so precautions must be taken to prevent electrolyte imbalances.

Recombinant factor VIIa is useful in individuals with congenital and acquired disorders of platelet function, particularly in patients in whom platelet

transfusion is ineffective. Recombinant factor VIIa increases the generation of thrombin at the site of damage to the vessel wall, thereby enhancing the recruitment of platelets. In individuals who have excessive mucocutaneous bleeding and in patients who are undergoing surgical procedures involving tissues of high fibrinolytic activity (e.g., nose, mouth, throat, and extraocular tissues), ε aminocaproic acid (5 g orally followed 1 hour later by 1 to 1.25 g/hour orally for 8 hours or until bleeding is controlled; maximum dose of 30 g/day), or tranexamic acid (15 to 25 mg/kg orally three times daily) can be useful.

HEREDITARY VASCULAR HEMORRHAGIC DISORDERS

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Hereditary hemorrhagic telangiectasia, also known as Osler-Weber-Rendu syndrome, is an autosomal dominant disease with an estimated prevalence of approximately 1 in 5000. Hereditary hemorrhagic telangiectasia is characterized by vascular malformations involving the skin, nose, and gastrointestinal tract.

PATHOBIOLOGY

Sequence variations in a number of distinct genetic loci have been implicated in the pathogenesis of hereditary hemorrhagic telangiectasia. The affected genes encode proteins involved in regulating the signaling of the transforming growth factor (TGF-)β superfamily within endothelial cells.[21] A majority of patients (about 85%) have mutations of *ENG*, which encodes endoglin, or *ACVRL1*, which encodes activin receptor-like kinase (ALK1). Cumulatively, more than 500 different mutations of *ENG* or *ACVRL1* have been identified. Although all classical features can be seen in patients with either *ENG* (hereditary hemorrhagic telangiectasia type 1) or *ACVRL1* (hereditary hemorrhagic telangiectasia type 2) mutations, some genotype-phenotype correlations have been reported. For example, pulmonary and cerebral anterior venous malformations appear to be more common in type 1. Mutations affecting SMAD4 have also been described in a minority (2 to 3%) of patients and are associated with a concomitant precancerous state of juvenile polyposis.

CLINICAL MANIFESTATIONS

Vascular abnormalities are typically visible on the face and fingers (Fig. 159-3). Telangiectasia in the nose is associated with regular episodes of epistaxis that can be prolonged and severe in nature, and telangiectasia in the bowel can cause significant gastrointestinal bleeding (Chapter 121). As a result of recurrent bleeding, patients commonly have secondary iron-deficiency anemia (Chapter 145). The majority of patients with hereditary hemorrhagic telangiectasia also develop larger arteriovenous malformations within the brain, lungs, and liver. These malformations can contribute to pulmonary artery hypertension (Chapter 69), high-output heart failure (Chapter 45), and an increased risk for venous thrombosis.

DIAGNOSIS

Epistaxis and telangiectasias constitute the most common symptoms and signs of hereditary hemorrhagic telangiectasia and are part of standardized diagnostic criteria (Table 159-5). Telangiectasias and risk of gastrointestinal bleeding tend to become more apparent with aging, but the clinical diagnosis can be challenging in younger individuals, in whom genetic testing can be definitive.[22]

TABLE 159-5 DIAGNOSTIC CRITERIA FOR HEREDITARY HEMORRHAGIC TELANGIECTASIA

Recurrent spontaneous epistaxis
Multiple skin telangiectasias
Arteriovenous malformations (e.g., in lungs, brain, stomach, liver, intestines, spinal cord)
First-degree relative with the disease

Definitive disease = 3 or more criteria; possible disease = 2 criteria.

TREATMENT

Patients with epistaxis should use moisturizing topical therapies to humidify the nasal mucosa. Timolol gel (0.5 mL of 1% gel twice daily by syringe)[A2] and bevacizumab (7.5 mg/kg intravenously every 2 weeks)[A3] may be useful. Oral tranexamic acid (1 g three times daily) under expert guidance is effective, and local ablative therapies may be useful for significant epistaxis.[23] Patients with gastrointestinal bleeding require endoscopic evaluation (Chapter 120). Hemoglobin and ferritin levels should be closely monitored, and adequate iron replacement therapy must be given.

EHLERS-DANLOS SYNDROME

Ehlers-Danlos syndrome, which also can cause blood vessel rupture, is discussed in Chapter 239.

ACQUIRED VASCULAR HEMORRHAGIC DISORDERS

Patients with acquired vascular hemorrhagic disorders typically have no prior personal or family history of bleeding. Henoch-Schönlein purpura (Chapter 406) typically presents with a palpable lower extremity purpura, associated with arthralgias, abdominal pain, and renal injury. Scurvy (Chapter 199) typically presents with petechiae or bruising and with tiny perifollicular hemorrhages around corkscrew hairs. In senile purpura, diminished vascular support owing to aging and sun exposure result in easy bruising, especially on the dorsa of hands, forearms, and lower legs.

160 COAGULATION FACTOR DEFICIENCIES

MARGARET V. RAGNI

COAGULATION DEFICIENCIES

Severe coagulation deficiencies, or coagulopathies, are typically characterized by spontaneous or provoked bleeding, such as during surgery or trauma, and may result in life- or limb-threatening complications. By contrast, moderate and mild coagulopathies may remain clinically silent until they are detected coincidentally on routine laboratory screening tests (e.g., prothrombin time [PT], activated partial thromboplastin time [aPTT]), or when these tests are ordered to evaluate the cause of abnormal bleeding or bruising.

In general, coagulopathies may result from inadequate synthesis of coagulation factor proteins or from inhibition of activated factor proteins by acquired antibodies or anticoagulant medications. Qualitative defects, either congenital or acquired, may also result in bleeding.

Much of the morbidity of coagulopathies can be minimized or avoided altogether by prophylactic replacement of the deficient clotting factor proteins. In contrast to the lifelong clinical manifestations of hereditary or congenital coagulopathies, acquired deficiencies usually appear acutely in previously asymptomatic individuals; they may not be suspected and often remit spontaneously or after eradication of an inciting disease state or withdrawal of an offending medication. Acquired coagulation disorders may be associated with more severe bleeding than congenital disorders, in part because of the delay in diagnosis.

HEREDITARY HEMOPHILIAS

DEFINITION

Hemophilia A and hemophilia B are caused by deficiencies or defects in clotting factor VIII (antihemophilic factor) and factor IX (antihemophilic factor B, or Christmas factor), respectively.[1] A deficiency of either of these intrinsic coagulation pathway proteins results in inadequate formation of thrombin at sites of vascular injury.

EPIDEMIOLOGY

Hemophilia A and B are sex-linked recessive disorders estimated to occur in 1 in 5000 and 1 in 30,000 male births, respectively. The higher incidence of hemophilia A may be due to the greater amount of DNA at risk for mutation in the large factor VIII gene (186,000 base pairs) compared with the factor IX gene (34,000 base pairs). Hemophilia A and B are observed in all racial and ethnic groups, and more than 20,000 individuals are affected in the United States. A substantial proportion (30%) of hemophilia cases arise as new, spontaneous mutations. Overall, the hemophilias are much more common than the autosomal recessive coagulation disorders (see later), which often affect progeny from consanguineous relationships and require the inheritance of two defective alleles for the bleeding manifestations to become evident.

PATHOBIOLOGY

Genetics

As with other sex-linked recessive diseases, the genes for factor VIII and factor IX are located on the long arm of the X chromosome. Males with a defective allele on their single X chromosome transmit this gene to all their daughters, who are then obligate carriers, but to none of their sons. Because the offspring of female carriers inherit one affected X chromosome, half of their sons develop the coagulation disorder, and half of their daughters are obligate carriers. Female carriers may manifest bleeding symptoms, particularly postpartum bleeding, if the alleles on the X chromosome are unequally inactivated (lyonization), if the defective hemophilic allele is expressed in preference to the normal allele, and if plasma factor VIII levels are below 50%. Female hemophilia may arise as a result of mating between a hemophilic male and a female carrier (homozygous for the defective factor VIII or IX gene) or in carrier females who have the 45,XO karyotype (Turner syndrome) and are hemizygous for the defective hemophilia gene.

No single mutation is responsible for the hemophilias. Many missense and nonsense point mutations, deletions, and inversions have been described. Severe molecular defects predominate, with 40 to 50% of all cases of severe hemophilia A evolving from a unique inversion of intron 22 (the largest of the factor VIII introns). This inversion results from the recombination and translocation of DNA within intron 22 of the factor VIII gene, with areas of extragenic but homologous "nonfunctional" DNA located at a distance from intron 22. Other less common severe molecular defects include large gene deletions (5 to 10% of cases) and nonsense mutations (10 to 15% of cases). The encoded proteins resulting from these mutations are defective and do not express any factor VIII activity. Mild or moderate hemophilia A is commonly associated with point mutations and deletions. In contrast, factor IX mutations are more diverse, and severe hemophilia B is more likely caused by large deletions. Mutated clotting factor genes responsible for the hemophilias may also encode for the production of defective nonfunctional proteins that circulate in the plasma and are detected at normal quantitative levels by immunoassays but not by functional activity assays. A listing of the mutations that cause the hemophilias can be accessed via the Human Gene Mutation Database (www.hgmd.org).

CLINICAL MANIFESTATIONS

Hemophilia A and hemophilia B are clinically similar, with clinical severity corresponding inversely to the circulating levels of plasma coagulant factor VIII or IX activity. However, hemophilia A is associated with a higher frequency of bleeding, a greater need for factor replacement therapy, and more frequent hospitalizations, thereby suggesting greater clinical severity than in hemophilia B. Individuals with less than 1% of normal factor VIII or IX activity are classified as having "severe" disease, which is characterized by frequent spontaneous bleeding events in joints (hemarthrosis) and soft tissues and by profuse hemorrhage with trauma or surgery. Although spontaneous bleeding is uncommon in mild deficiencies (>5% normal activity), excess bleeding typically occurs with trauma or surgery. A moderate clinical course is associated with factor VIII or IX levels between 1 and 5%. Approximately 60% of all cases of hemophilia A are clinically severe, whereas only 20 to 45% of cases of hemophilia B are severe.

Severe hemophilia is typically suspected and diagnosed during infancy in the absence of a family history. Among newborns, intracranial hemorrhage is the leading cause of morbidity and mortality, with a cumulative incidence of about 4%. Intracranial hemorrhage does not appear to be related to the mode of delivery, although half of such hemorrhages occur in the newborn period. Circumcision within days after birth is accompanied by excessive bleeding in less than half of severely affected boys. The first spontaneous hemarthrosis in severely affected hemophilic boys usually occurs between 9 and 18 months of age, when ambulation begins. In moderately affected individuals, it generally does not occur until 2 to 5 years of age. The knees are the most prominent sites of spontaneous bleeds, followed by the elbows, ankles, shoulders, and hips; wrists are less commonly involved. Female carriers may also sustain joint bleeding and hemarthrosis, often unrecognized until years later, with sports and/or trauma.

Acute hemarthroses (Fig. 160-1) originate from the subsynovial venous plexus underlying the joint capsule and produce a tingling or burning sensation, followed by the onset of intense pain and swelling. On physical examination, the joint is swollen, hot, and tender to palpation, with erythema of the overlying skin. Joint mobility is compromised by pain and stiffness, and the joint is usually maintained in a flexed position.

FIGURE 160-1. Acute hemarthrosis of the knee is a common complication of hemophilia. It may be confused with acute infection unless the patient's coagulation disorder is known, because the knee is hot, red, swollen, and painful. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

ABSTRACT

Rare congenital and acquired bleeding disorders require an understanding of their coagulation pathways, clinical manifestations, and strategies for prevention and treatment of bleeding. Recombinant factor therapies, some with an extended half-life, and novel therapeutics are FDA approved or in clinical trials. Adeno-associated virus (AAV) gene therapy is achieving durable factor expression, and gene editing is underway in animal models. Both of these approaches could reduce or eliminate the need for the infusion of factors in the future.

KEYWORDS

hemophilia A
hemophilia B

lupus anticoagulant
antiphospholipid syndrome

Recurrent or untreated bleeds result in chronic synovial hypertrophy and, eventually, damage to the underlying cartilage, with subsequent subchondral bone cyst formation, bony erosion, and flexion contractures. Abnormal mechanical forces from weight bearing can produce subluxation, misalignment, loss of mobility, and permanent deformities of the lower extremities (Fig. 160-2). These changes are accompanied by chronic pain, swelling, arthritis, and disability. Plain radiographs and clinical examination of chronic hemarthroses often underestimate the extent of bone and joint damage; serial magnetic resonance imaging is the most sensitive technique to detect and monitor early and progressive disease, and early musculoskeletal ultrasound, performed in the office setting, may detect early joint disease even before symptoms occur.

Intramuscular hematomas account for about 30% of hemophilia-related bleeding events and are rarely life-threatening. Hematomas are usually precipitated by physical or iatrogenic trauma (e.g., after intramuscular injections) and may compromise sensory and motor function or arterial circulation if they entrap and compress vital structures in closed fascial compartments. The latter occurrence, termed *compartment syndrome*, presents with the rapid onset of swelling and severe pain in an extremity, unrelieved by factor infusion and standard analgesics, and is considered a medical emergency that may require fasciotomy to preserve tissue viability and provide pain relief. Retroperitoneal hematomas may be confused clinically with appendicitis or hip bleeds but should be suspected in a patient who is unable to stand erect due to the pain of muscle extension in the presence of hematoma. Immediate and aggressive treatment is required to prevent permanent anatomic deformity, such as flexion contracture, nerve damage, or pseudotumor formation (expanding hematomas that erode and destroy adjacent skeletal structures).

Bleeding from mucous membranes is not uncommon and when it involves the tongue or the retropharyngeal space, may threaten the airway. Gastrointestinal hemorrhage typically originates from anatomic lesions proximal to the ligament of Treitz and may be exacerbated by esophageal varices and/or thrombocytopenia secondary to cirrhosis and portal hypertension, or by the use of nonsteroidal anti-inflammatory drugs (NSAIDs) for the treatment of hemarthroses. Spontaneous bleeding in the genitourinary tract may arise from ureteral clots, renal stones, and/or less commonly, infection.

Intracranial bleeds occur in 10% of patients with a risk of 2% per year; they may be spontaneous or traumatic and are fatal in 30% of cases. Neuromuscular defects, seizure disorders, and intellectual deficits may ensue.

DIAGNOSIS

The diagnosis of hemophilia is suspected on the basis of a family and personal bleeding history and laboratory detection of prolongation of the aPTT (with normal PT). It is confirmed by significantly reduced plasma factor VIII or IX activity. As noted in Chapter 157, the aPTT is not a sufficiently sensitive screening test to be prolonged in mild hemophilia, where the factor VIII level is sometimes greater than 30% of normal. Severe hemophilia is usually recognized in infancy, with circumcision bleeding; by contrast, moderate or mild disease is recognized later in life after trauma or surgery. Hemophilia can be distinguished from von Willebrand disease (VWD; Chapter 159) by normal ristocetin cofactor and von Willebrand factor antigen levels. In type 2N VWD, the factor VIII level is significantly lower than ristocetin cofactor and von Willebrand factor antigen levels due to reduced factor VIII binding; this variant of VWD may require genotyping to distinguish it from hemophilia A. Other congenital intrinsic factor deficiencies (e.g., factor XI and XII) can be determined by coagulation factor–specific assays. Vitamin K deficiency (see later and Chapter 161) can be detected by the associated PT prolongation; deficiencies of factors II, VII, IX, and X; and resolution of the coagulation defect with vitamin K. The presence of heparin can be confirmed by correction of the aPTT after running the sample over a heparin absorption column. Failure of the aPTT to correct in a 1:1 mix with normal plasma suggests the presence of an inhibitor; specific inhibitors are associated with a single decreased factor level (usually factor VIII; see Alloantibody Inhibitors to Factors VIII and IX under Treatment), whereas blocking inhibitors cause nonspecific factor level changes associated with a positive hexagonal lipid assay (see Antiphospholipid Syndrome and Lupus Anticoagulant).

FIGURE 160-2. Severe chronic arthritis in hemophilia. The knee is the most commonly affected joint. Both knees are severely deranged in this patient. Note that the patient is unable to stand with both feet flat on the floor. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

TREATMENT AND PREVENTION

General Care

Individuals with hemophilia cared for at hemophilia treatment centers have lower mortality and reduced costs of care compared with those receiving treatment elsewhere. The chronic care model practiced at hemophilia treatment centers emphasizes prevention to reduce joint disease and complications, optimization of factor dosing, counseling regarding safe sports, and the avoidance of aspirin and other drugs that inhibit platelet function, as well as management of surgical procedures and chronic transfusion-transmitted infections, including hepatitis C and HIV infection.

Treatment and Prevention of Bleeding

Replacement of Clotting Factors

Treatment and prevention of acute bleeding events in hemophilia A and B are based on replacement of the missing or deficient clotting factor protein to restore adequate hemostasis (Table 160-1). Use of factor on a prophylactic basis several times weekly to prevent bleeds can reduce or prevent joint bleeds and reduce joint arthropathy. All clotting factor concentrates available in the United States, whether plasma-derived or genetically engineered, are considered extremely safe; none has been implicated in the transmission of bloodborne viral pathogens or prions.

The goal of replacement therapy (see Table 160-1) is to achieve plasma factor VIII or IX activity levels that are sufficient to prevent spontaneous bleeds. As these events are individualized and vary by age, level of activity, and pharmacokinetics, the optimal level of treatment may vary among affected patients. In general, however, activity levels of 15% are sufficient to prevent spontaneous bleeding, whereas factor activity levels of 25 to 30% are recommended to treat minor spontaneous or traumatic bleeds (e.g., hemarthroses, persistent hematuria). At least 50% clotting factor activity levels are recommended for severe bleeds (e.g., major dental surgery, maintenance replacement therapy after major surgery or trauma), and 80 to 100% activity for any life-threatening or limb-threatening hemorrhagic event (e.g., major surgery, trauma). After major trauma or if visceral or intracranial bleeding is suspected, replacement therapy adequate to achieve 100% clotting factor activity should be administered immediately (within 5 to 10 minutes) *before* diagnostic procedures are initiated.

To calculate the initial dose of replacement factor, plasma factor VIII activity generally increases about 2% (0.02 IU/mL) for each unit of factor VIII administered per kilogram of body weight, and factor IX activity increases about 1% (0.01 IU/mL) for each unit of factor IX administered per kilogram of body weight. Therefore, a 70-kg individual with severe hemophilia A or B (factor VIII or IX activity <1% of normal) who requires replacement to 100% activity for major surgery should initially receive 3500 IU of factor VIII or 7000 IU of factor IX concentrate. The circulating half-lives of factors VIII and IX require subsequent dosing at half the initial dose every 8 to 12 hours for factor VIII and every 18 to 24 hours for factor IX, respectively. However, this empirical dosing should be individualized according to the patient's peak recovery and trough activity levels, using population pharmacokinetic modeling. The frequency of repeat dosing is also determined by the rapidity of pain relief, recovery of joint function, and resolution of active bleeding. Heterogeneity in the half-life of factor VIII concentrates is due to variability in clearance of von Willebrand factor.[2]

Replacement is usually maintained for at least 10 to 14 days after major surgery to allow proper wound healing and to avoid postoperative bleeding. In

TABLE 160-1 FDA-APPROVED COAGULATION PROTEINS AND REPLACEMENT THERAPIES AVAILABLE IN THE UNITED STATES

COAGULATION PROTEIN DEFICIENCY	INHERITANCE PATTERN	PREVALENCE	MINIMUM HEMOSTATIC LEVEL	REPLACEMENT SOURCES
Factor I (fibrinogen) Afibrinogenemia Dysfibrinogenemia	 Autosomal recessive Autosomal dominant or recessive	 Rare (<300 families) Rare (>300 variants)	50-100 mg/dL	Cryoprecipitate, FFP, fibrinogen concentrate
Factor II (prothrombin)	Autosomal dominant or recessive	Rare (25 kindreds)	30% of normal	FFP, factor IX complex concentrates
Factor V (labile factor)	Autosomal recessive	1 in 1 million births	25% of normal	FFP
Factor VII	Autosomal recessive	1 in 500,000 births	25% of normal	Recombinant factor VIIa (15-20 μg/kg), FFP, factor IX complex concentrates
Factor VIII (antihemophilic factor)	X-linked recessive	1 in 5000 male births	80-100% for surgery/life-threatening bleeds, 50% for serious bleeds, 25-30% for minor bleeds	Factor VIII concentrates (recombinant and recombinant extended-half-life factor VIII preferred)
Von Willebrand disease (also see Chapter 159) Type 1 and 2 variants Type 3	 Usually autosomal dominant Autosomal recessive	 1% prevalence 1 in 1 million births	>50% VWF antigen and ristocetin cofactor activity	DDAVP for mild to moderate disease (except type 2B; variable response in 2A); cryoprecipitate and FFP (not preferred, except in emergencies); plasma-derived factor VIII/VWF concentrate, viral attenuated, intermediate purity; recombinant VWF concentrate (the latter two proteins preferred for surgery, for disease unresponsive to DDAVP and for type 3)
Factor IX (Christmas factor)	X-linked recessive	1 in 30,000 male births	25-50% of normal, depending on extent of bleeding, surgery	Factor IX concentrates (recombinant and recombinant extended half-life factor IX preferred); FFP not preferred except in dire emergencies
Factor X (Stuart-Prower factor)	Autosomal recessive	1 in 500,000 births	10-25% of normal	Plasma-derived factor X concentrate, FFP, or factor IX complex concentrates
Factor XI (hemophilia C)	Autosomal dominant; severe type is recessive	4% of Ashkenazi Jews; 1 in 1 million general population	20-40% of normal	FFP or factor XI concentrate
Factor XII (Hageman factor), prekallikrein, high-molecular-weight kininogen	Autosomal recessive	Not available	No treatment necessary	—
Factor XIII (fibrin stabilizing factor)	Autosomal recessive	1 in 3 million births	5% of normal	Recombinant FXIII concentrate, FFP, cryoprecipitate, or viral-attenuated factor XIII concentrate

DDAVP = desmopressin; FDA = U.S. Food and Drug Administration; FFP = fresh-frozen plasma; VWF = von Willebrand factor.

the management of bleeds or surgical procedures in patients with hemophilia, either repetitive bolus injections, as described earlier, or continuous infusion can be used for delivery of clotting factor replacement. The latter can provide constant levels of the deficient coagulation factor and can be cost-effective. Extended half-life recombinant factor VIII and IX[3] (including pegylated, albumin-fusion, nonacog alfa [factor IX], or Fc-fusion [Fc domain of immunoglobulin G_1, IgG_1]) are also available for prophylaxis or treatment, as they are safe and effective in reducing bleed frequency and prolong half-life 1.5- to 2-fold for factor VIII and 2.5- to 5.0-fold for factor IX. These agents have also been used successfully in surgery, but they are costly and may not be available at many hospitals. The typical dose frequency for extended half-life recombinant factor VIII is twice weekly at a dose of 50 to 65 IU/kg; for extended half-life recombinant factor IX, the dose is once every 1 to 2 weeks at a dose of 100 IU/kg.

Other Approaches to Augment Clotting

Nonfactor therapeutics given by subcutaneous administration also can be used as prophylaxis to prevent clinical bleeding. Emicizumab, which is the only such agent currently FDA-approved, is a bispecific monoclonal antibody that bridges activated factor IX and factor X to replace the function of missing activated factor VIII, whether due to a factor VIII inhibitor or factor VIII deficiency in hemophilia A. Emicizumab prophylaxis (1.5 mg/kg subcutaneously weekly or 3.0 mg/kg every 2 weeks, or 6.0 mg/kg every 4 weeks) is effective in reducing clinical bleeding in hemophilia A among patients of all ages, with or without inhibitors.[A1–A3] However, emicizumab is effective only for prevention but not for the treatment of acute bleeds. For acute treatment of bleeds or surgery in patients receiving emicizumab, factor replacement is required urgently. A novel intravenous factor VIII fusion protein, efanesoctocog alfa, in which recombinant factor VIIIFc is fused to von Willebrand factor, results in a four-fold increase in the half-life of factor VIII, thereby suggesting the possibility of weekly intravenous dosing.[4]

Hemarthroses

For hemarthroses, immediate or early replacement of the deficient clotting factor to normal hemostatic levels rapidly reverses the pain, whereas delayed treatment results in excess pain, morbidity, and joint damage. Optimal management once a bleed occurs includes rest, ice, (factor) concentrate, and elevation,[5] as well as protective mechanotherapy for balanced and incremental rehabilitation of injured tissues.[6]

The moderate or severe pain that accompanies acute hemarthroses responds to immediate analgesic relief. Narcotic analgesics, such as codeine or synthetic derivatives of codeine, are avoided because of their addictive potential, and early consultation with pain service physicians is recommended. Chronic acetaminophen analgesia, although helpful in low doses, may be associated with hepatic toxicity as higher doses are used, especially in patients with chronic hepatitis. For some patients compliant with prophylaxis, nonsteroidal anti-inflammatory drugs (NSAIDs; Table 26-4) may be used provided that bleeding does not occur. Aspirin (ASA) is generally contraindicated as it irreversibly inhibits platelet aggregation.

Over 75% of children and about 50% of adults engage in prophylaxis (preventive) factor infusions several times a week to maintain factor VIII or IX levels above 1% to prevent joint bleeds and the development of chronic hemophilic arthropathy. However, prophylaxis must be initiated before 4 years of age, the earlier the better, and in the absence of obesity to preserve joint motion.[7] For

optimal outcomes, the patient and/or parent should be involved in decision making and the treatment plan.[8]

Although prophylaxis is the optimal strategy to prevent pain, reduced motion, and the disability of end-stage joint destruction, when prophylaxis has failed or was never initiated, surgery may be recommended. Synovectomy through open surgery or arthroscopy removes the inflamed tissue and may decrease pain and reduce recurrent bleeding, but usually only temporarily. Nonsurgical synovectomy (synoviorthosis), which involves the intra-articular administration of a radioisotope, may be considered in high-risk patients and for patients who have alloantibody inhibitors to factor VIII or IX (see later). Neither synovectomy nor synoviorthosis reverses joint damage, but both procedures may delay its progression. Non–weight-bearing exercises, such as swimming and isometrics, are important for periarticular muscle development and maintenance of joint stability for ambulation. Intractable pain and severe joint destruction secondary to repeated hemorrhage require prosthetic replacement. Chronic ankle pain responds best to open surgical or arthroscopic fixation and fusion (arthrodesis).

Genitourinary Bleeding

For genitourinary bleeding, clotting factor, fluid replacement, and, in children, a short course of steroids may be helpful to hasten resolution. However, genitourinary tract bleeding in patients with hemophilia may be worsened by the use of antifibrinolytic agents.

Alloantibody Inhibitors to Factors VIII and IX

Alloantibodies to infused factor VIII or, less frequently, to factor IX are usually detected in childhood after a median of 9 to 12 exposures to clotting factor. The prevalence of factor VIII alloantibodies among hemophilia A patients is 15 to 25%, whereas the prevalence of factor IX alloantibodies among hemophilia B patients is 1.5 to 3%.

Inhibitors are associated with hospitalization, cost, and early death. Inhibitors occur preferentially in patients who have a family history of inhibitors, patients who have large multidomain factor VIII and factor IX gene deletions, and in Black and Hispanic patients, but it is difficult to predict in whom inhibitors will develop. Among Black patients, gene sequence data suggest that mismatched factor VIII transfusions may account for the high risk of developing inhibitors. Nongenetic risk factors include early high-intensity or frequent daily exposure to factors to treat a bleed, trauma, or surgery. In previously untreated patients, the risk of developing inhibitors appears to be higher with recombinant than with plasma-derived factor.[A4]

Factor VIII–specific IgG1 antibodies appear first, followed by IgG3 and IgG4 antibodies. However, the appearance of factor VIII–specific IgG3 antibodies is always associated with the subsequent diagnosis of factor VIII inhibitors.[9]

The development of an alloantibody inhibitor is suspected when replacement therapy is ineffective in controlling bleeding symptoms. These antibodies completely neutralize clotting factor activity and prevent or reduce any increment in factor VIII or IX levels following bolus infusions of concentrate. Inhibitors are also associated with anaphylaxis and nephrotic syndrome.

Characterized as time and temperature dependent, inhibitors are quantitated in Bethesda units (BU). By definition, 1 BU is the amount of inhibitor that neutralizes 50% of the specific clotting factor activity in normal plasma. High responders, or patients with high-titer inhibitors (≥5 BU), mount an anamnestic antibody response to factor VIII clotting factor protein, usually within 5 to 7 days after subsequent exposure, and are no longer responsive to infused factor VIII. By contrast, low responders, or patients with low-titer inhibitors (<5 BU), do not manifest anamnesis, and such low-titer inhibitors can readily be overwhelmed by large amounts of human factor VIII or factor IX concentrate and can be successfully treated with three to four times the usual factor dose.

Management of patients with high-titer inhibitors[10] requires both assurance of hemostasis using bypass therapy and eradication of inhibitor formation (see Table 160-1). Bypass is typically accomplished with factor VIII inhibitor bypass activity (FEIBA; a plasma concentrate containing activated proenzymes of the prothrombin complex factors, prothrombin, and factors V11, IX and X). The usual treatment consists of one dose of FEIBA (75 IU/kg) or two doses of recombinant factor VIIa (90 to 270 μg/kg), although some patients may respond better to one agent than the other. Sequential use of FEIBA and recombinant factor VIIa (e.g., alternating every 6 hours) can improve hemostasis over single-agent treatment, but careful monitoring for thrombosis is necessary. The total dose of FEIBA should not exceed 20,000 IU in 24 hours.

Secondary prophylaxis in adults, with either recombinant factor VIIa, 90 μg/kg daily, 270 μg/kg daily, or FEIBA 85 IU/kg weekly, may significantly reduce bleeding rates as compared with on-demand treatment. Because neither agent is very effective alone and is limited by either total dose or dose frequency (VIIa must be given every 2 to 3 hours), these bypass agents may be alternated in selected patients (without cardiovascular risk, obesity, hypertension) every 3 hours for severe bleeds, surgery, or trauma. Alternatively, emicizumab prophylaxis (1.5 mg/kg subcutaneously weekly) may reduce bleeding events and improve quality of life compared with no prophylaxis in adults and children who have hemophilia A and have inhibitors.[A5,A6] By avoiding the need for factor VIII, inhibitor titers often decline.[11] Whether emicizumab and extended half-life agents such as recombinant factor VIIIFc will shorten the time to tolerance is currently uncertain. FEIBA should be avoided in patients who are receiving emicizumab because the combination increases the risk of thrombosis and thrombotic microangiopathy.

Eradication of inhibitors with immune tolerance induction is effective in about 75% of patients if initiated within 12 months of the detection of inhibitors. Immune tolerance induction regimens consist of daily factor concentrates (e.g., 200 IU/kg daily) to accomplish desensitization to infused factor. Immune tolerance induction is initiated as soon as the inhibitor is detected.[12] Maintenance of tolerance following induction usually, but not always, requires factor VIII or IX prophylaxis. Single or combination immunosuppressive agents (e.g., rituximab, mycophenolate, or cyclosporine) are variably effective. Other novel agents that promote thrombin generation by alternate pathways, including siRNA-antithrombin (fitusiran) and anti-TFPI, are in clinical trials to assess their safety and efficacy as potential bypass agents.[13] Preliminary data suggest bleeding frequency and factor use with these agents are reduced in inhibitor and noninhibitor patients.

Factor Concentrate–Transmitted Viral Infections

The prevalence of hepatitis C virus infection is about 90% in patients who were transfused from the late 1970s through the mid-1980s, and the prevalence of human immunodeficiency virus (HIV) infection is about 80% in patients who were transfused with factor VIII products and 50% in patients who were transfused with factor IX products from 1978 through the mid-1980s. Patients with HIV now can be controlled with highly active antiretroviral therapy (Chapter 357). Chronic hepatitis C infection (Chapter 135) remains the leading cause of death in hemophilia, in part because antiviral therapy does not prevent hepatocellular cancer in patients who have had long-standing chronic infection.

Ancillary and Other Therapies

Ancillary treatment strategies for the hemophilias include antifibrinolytic agents, such as ε-aminocaproic acid (50 mg/kg 3 to 4 times daily) or tranexamic acid (3 or 4 g orally daily in divided doses), to minimize mucous membrane bleeding, particularly in the oral cavity, and the application of fibrin glue to bleeding sites. Desmopressin (DDAVP) can be administered by nasal insufflation 30 minutes before a scheduled surgical procedure (one spray per nostril, to provide a total dose of 300 μg; or, in patients weighing less than 50 kg, 150 μg administered as a single spray). DDAVP may also be administered intravenously (dissolved in 50 mL normal saline) over 30 minutes at a dose of 0.3 μg/kg. DDAVP is especially useful in patients with mild hemophilia A because an adequate incremental rise in factor VIII activity can circumvent the use of clotting factor concentrates, and is generally available in most emergency department settings. Oral and intravenous fluid must be restricted to less than 1000 mL in any 24-hour period that DDAVP is administered whether to avoid hyponatremia and hyponatremic seizures. Other complications of DDAVP include facial flushing and tachyphylaxis (loss of response after three consecutive daily doses).

Gene Therapy for Hemophilia A and B

The hereditary hemophilias are model diseases for gene therapy[14] because they are caused by specific, well-defined gene mutations. A small, incremental rise in the synthesis of clotting factors can lead to substantially improved treatment and quality of life and inadvertent overexpression by successful gene transfer would not be detrimental.[15] Various adeno-associated (AAV) viral vectors carrying the Padua (FIX R338L) factor IX gain-of-function transgene in hemophilia B patients can achieve factor IX expression of 14 to 76% for up to 10 years.[16] In patients with severe hemophilia A, trials of AAV8-BDD-factor VIII and AAV5-BDD (B-domain deleted factor VIII)[17–19] have achieved factor VIII expression levels of 60% or higher for up to 3 years, but then waning to 20% or lower in some trials. These treatments resulted in a more than 90% reduction in annualized rate of bleeding events and use of factors in both hemophilia A and B. An immune response to the AAV capsid, associated with increases in liver aminotransferase levels, sometimes occurs but appears to be responsive to corticosteroids or possibly mycophenolate mofetil. Less immunogenic vectors, innovative delivery systems, and CRISPR gene editing are also being studied.

PREVENTION

Carrier Detection and Prenatal Diagnosis

Carrier detection and prenatal diagnosis have become technically feasible, very sensitive, and widely available. Noninvasive prenatal diagnosis by use of microfluidic digital PCR of maternal plasma DNA is based on the relative proportion of mutated versus normal alleles; it can detect an affected fetus as early as the eighth week of gestation. Because prenatal diagnosis requires the mother to have a known mutation, mothers are increasingly being tested in a nationwide hemophilia genotype program, MLOF (My Life, Our Future). However, at best only two thirds of carrier mothers will be identified because one third of new hemophilia cases arise as spontaneous mutations.

Early prenatal diagnosis is important to reduce intracranial bleeds in an infant with anticipated severe hemophilia by recommended caesarean delivery and to reduce circumcision-related bleeding by preventive factor treatment. Guidelines suggest caesarean section delivery be considered for any known male infants with severe hemophilia A. Vacuum extraction may increase cephalohematoma formation and is discouraged.

Early diagnosis is also important for the mother to reduce peripartum bleeding and advocate for genetic counseling regarding family planning. Next-generation sequencing, carrier testing, and prenatal diagnosis with genetic counseling are widely available in the United States through the network of federally funded hemophilia treatment centers. Fecundity rates remain high, and few confirmed carriers elect to terminate their pregnancies, even if an affected fetus is detected in utero. These decisions are influenced by the wide availability of safe and effective coagulation factor replacement concentrates and by the prospect of an eventual cure for the hemophilias through gene transfer or gene editing.

PROGNOSIS

The life expectancy of individuals with severe hemophilia is similar to that of the normal population. Although deaths from HIV and hepatitis C are declining, in part due to effective antiretroviral therapy for HIV (Chapter 357) and effective combination antiviral treatment for hepatitis C, patients with hemophilia and long-standing chronic hepatitis C infection prior to elective treatment still have a somewhat increased risk of hepatocellular carcinoma despite antiviral therapy.[20] Further, as patients with hemophilia live longer, malignancy and heart disease are becoming more common, and with them need for additional replacement during periods of chemotherapy-induced thrombocytopenia or antiplatelet therapy.[21] Among patients with alloantibody inhibitors, mortality rates are significantly higher than in other patients, so early diagnosis and early immune tolerance induction are recommended. Bleeding is also a leading cause of death, with a lifetime risk of intracranial hemorrhage of approximately 2 to 8%. Finally, the usual problems of aging are increasingly being recognized in those with hemophilia, including atherosclerosis, hypertension, hyperlipidemia, obesity, and diabetes. The impact of these conditions on the natural history of hemophilia, given several studies suggesting lower mortality from ischemic heart disease, remains to be seen.

ACQUIRED HEMOPHILIAS

EPIDEMIOLOGY AND PATHOBIOLOGY

Autoantibody inhibitors occur spontaneously in individuals with previously normal hemostasis. In contrast to alloantibody inhibitors in hemophilic men, which are directed against exogenous clotting factor, autoantibody inhibitors are directed against endogenous clotting factor, most commonly factor VIII. These autoantibodies typically arise in individuals with no past bleeding history, so the diagnosis may be missed until prolonged aPTT and aPTT mixed tests are obtained (Chapter 157). Although 50% of patients with autoantibody inhibitors have no obvious underlying cause, the other 50% are associated with autoimmune diseases, lymphoproliferative disorders, idiosyncratic drug reactions, pregnancy, and advanced age.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Massive hemorrhagic events, even more severe than in hemophilia patients with alloantibodies, and more commonly in soft tissues, may occur in those with autoantibodies because of a delay in diagnosis and treatment. The laboratory expression of autoantibodies is similar to that of alloantibodies, except that clotting factor activity is not completely neutralized. Residual clotting factor activities between 3 and 20% of normal are frequently observed in patients with autoantibodies.

TREATMENT

The same principles of replacement therapy for alloantibodies apply to these acquired autoantibody inhibitors.[22] The two goals of treatment are to stop the bleeding, assure hemostasis, and eradicate the inhibitor. For hemostasis, recombinant factor VIIa, activated prothrombin complex concentrate, or factor VIII bypass activity is commonly used, in similar doses used to achieve hemostasis with a success rate in over 90% of patients and thrombotic events in less than 5%. Emicizumab (3 mg/kg subcutaneously for 2 to 3 doses followed by 1.5 mg/kg every 3 weeks) can also be an effective prophylactic hemostatic therapy.[23]

Eradication of the inhibitor is significantly more successful (about 80%) in patients who are treated with corticosteroids (e.g., prednisone 1 mg/kg/day orally) and cyclophosphamide (150 mg/day orally or 500 to 750 mg/m^2 intravenous bolus every 3 to 4 weeks) than with corticosteroids alone (about 60%), with dose titration based on inhibitor levels and complicating cytopenias. Rituximab-based regimens (375 mg/m^2 intravenously weekly for 4 weeks) are also effective in about 60% of patients. High-dose intravenous immunoglobulin (IVIg)–based regimens under expert supervision may be effective in about 45% of patients. These agents are tapered and discontinued once the autoantibody has disappeared. The time to complete remission is about 5 weeks for corticosteroids plus cyclophosphamide, whereas rituximab-based regimens require twice as long to achieve remission.

PROGNOSIS

Patients with acquired hemophilia have a mortality rate of 15 to 25%, which is considerably higher than that observed with alloantibody factor VIII inhibitors. Survival in acquired hemophilia is influenced primarily by the achievement of a complete remission, age younger than 65 years at diagnosis, and any related diseases (malignancy vs. postpartum vs. others). Hemorrhagic complications are the primary cause of death, but about 15 to 20% of deaths are associated with sepsis, and about 70% of cases of sepsis arise as a complication of cyclophosphamide-induced neutropenia that may be avoided with future therapies.

VON WILLEBRAND DISEASE

The most common congenital bleeding disorder is von Willebrand disease, which is discussed in detail in Chapter 159.

FACTOR XI DEFICIENCY

EPIDEMIOLOGY

Factor XI deficiency has a prevalence of 1 in 1 million in the general population and 1 in 500 births in Ashkenazi Jewish families. The intrinsic pathway of coagulation of factor XI is the only contact-phase component that is associated with excessive bleeding complications when a deficiency exists.

PATHOBIOLOGY

Factor XI deficiency is predominantly an autosomal recessive trait, although some mutations may have a dominant transmission pattern. The factor XI gene (*FXI*) is located on chromosome 4, and the protein circulates as a homodimer, with each FXI monomer composed of four apple domains encoded by exons 3 through 10 and a protease domain encoded by exons 11 through 15. The Glu117 stop mutation in *FXI* is the most common cause of factor XI deficiency, due to poor secretion or stability of the truncated protein or decreased levels of messenger RNA. More than 170 mutations of *FXI* have been identified in factor XI–deficient patients (see www.factorxi.org), but close correlation between bleeding phenotype and genotype is lacking. Most mutations are missense or nonsense mutations and are located across all four apple domains and the serine protease region.

In Ashkenazi Jewish individuals, factor XI deficiency is common, with a heterozygote frequency of 8 to 10%; two predominant gene mutations occur with equal frequency and are designated type II (a stop codon in exon 5) and type III (a single base defect in exon 9). The most severe clinical disease is observed in patients who are homozygous for type II and who usually have less than 1% factor XI activity. Homozygous type III individuals also manifest severe symptoms, but typically less severe than those of type II patients; they have slightly higher factor XI levels of about 10 to 20%. Compound heterozygotes, type II/III, make up the bulk of factor XI–deficient patients; they have clinically mild disease, with factor XI levels between 30 and 50%.

In individuals of non-Ashkenazi Jewish ancestry, the mutations are more variable, although Cys128 stop has been described in several kindreds, and Cys38Arg has been found in several French Basque families. One third of patients who develop inhibitors are homozygous for Glu117 stop, which results in an absent *FXI*. Genotypic identification of affected patients is determined by measuring factor XI levels rather than by defining the specific gene defect.

CLINICAL MANIFESTATIONS

The clinical bleeding tendency in factor XI deficiency is less severe than that observed in severe hemophilia A or B and, in contrast to the hemophilias, does not correlate with the severity of the deficiency. Most individuals with less than 20% of normal factor XI activity experience excessive bleeding after trauma or surgery, but a few do not bleed. In contrast, bleeding has been observed in approximately 35 to 50% of mildly affected patients with factor XI levels between 20 and 50% of normal. Spontaneous hemorrhagic episodes, hemarthroses, and intramuscular and intracerebral bleeds are unusual; traumatic and surgical bleeds typically involve the mucous membranes. Patients undergoing tonsillectomy, prostatectomy, or dental extraction are at highest risk for bleeding unless replacement therapy is administered. Women may experience significant menorrhagia, and women with menorrhagia should be screened for both von Willebrand disease and factor XI deficiency. Patients with mild factor XI deficiency and coincident mild von Willebrand disease have an increased risk of bleeding.

DIAGNOSIS

Factor XI deficiency is diagnosed by a prolonged activated partial thromboplastic time (aPTt), normal prothrombin time (PT), and decreased factor XI activity ascertained in a specific quantitative clotting assay (normal range, 60 to 130%).

TREATMENT

Not all individuals with factor XI deficiency bleed, so it may be reasonable to monitor affected individuals with no treatment, especially if they have no family history of bleeding. For surgical or other major bleeding, fresh frozen plasma 15 to 20 mL/kg may be given, although potential complications include fluid overload and infection risk, which can be reduced with the use of pathogen-inactivated fresh frozen plasma,[24] if available. Use of factor XI concentrate, which is available in Europe but not the United States, may be complicated by thrombosis, which occurs in approximately 10% of patients, particularly in older individuals with preexisting cardiovascular disease or malignancy. Replacement dosing levels should not exceed 70% of factor XI activity. Repeat dosing with fresh frozen plasma or factor XI concentrate should take into consideration the long (60- to 80-hour) biologic half-life of factor XI in vivo.

The decision to treat heterozygotes with factor XI at levels greater than 20% is empirical and should be based on personal history of bleeding after trauma or surgery. There is no clear evidence that suggests any benefit of DDAVP. Because hemorrhagic complications originate most commonly from mucous membrane surfaces, antifibrinolytic agents such as ε-aminocaproic acid or tranexamic acid under expert supervision are frequently helpful as adjunctive therapy. In women with menorrhagia or postpartum hemorrhage, testing for von Willebrand disease is recommended because both diseases may be present, but testing should be postponed until 6 to 8 weeks after delivery to avoid hormone-induced increase in von Willebrand factor levels that may mask diagnosis.

Alloantibody inhibitors, which neutralize the hemostatic effects of exogenously administered factor XI replacement, can develop in patients with severe factor XI deficiency who have been exposed to plasma or factor XI concentrate. Recombinant factor VIIa can prevent bleeding during or after surgery in these patients.

DEFICIENCIES OF CONTACT ACTIVATION FACTORS

Although factor XI plays an important role in the activation of factor IX in the intrinsic pathway generation of thrombin, it is only one of the four components of the contact phase of coagulation (Chapter 157). Deficiencies in any of the other three factors (factor XII, prekallikrein, and high-molecular-weight kininogen) produce in vitro laboratory abnormalities. Even among those with severe factor XII deficiency (<1% activity), clinical bleeding does not occur. In fact, up to 8 to 10% with severe factor XII deficiency actually experience venous thromboembolic events, which are occasionally fatal. This finding has led to speculation that factor XII deficiency may lead to hypercoagulability through defective participation of the contact-phase proteins in the activation of fibrinolysis.

DIAGNOSIS

Deficiencies of each of these factors prolong the aPTT, often markedly, but it may normalize after prolonged incubation of the patient's plasma at 37° C with a negatively charged activator of the aPTT assay (i.e., kaolin or celite). Specific assays are also available to quantitate each of the contact factors.

TREATMENT

Deficiencies of the contact activation factors, however severe they are and however prolonged the associated aPTT may be, do not cause clinical bleeding problems, even in response to surgery or trauma. Therefore, no therapy is indicated for factor XII deficiency, prekallikrein deficiency, or high-molecular-weight kininogen deficiency. Routine anticoagulation regimens are used to treat thrombotic events.

FACTOR XIII (FIBRIN-STABILIZING FACTOR) DEFICIENCY

Factor XIII is a transglutaminase that is activated by thrombin and functions to cross-link fibrin to protect it from lysis by plasmin, the key enzyme of the fibrinolytic system. It is also involved in normal wound healing and tissue repair and seems to be crucial for maintaining a viable pregnancy. Homozygous severe deficiency states are rare and are inherited in an autosomal recessive manner, with a prevalence of 1 per 3 million births. Consanguinity is common. Most patients are deficient in the A-subunit (FXIII-A). Half of the molecular defects that account for A-subunit deficiency are missense mutations.

CLINICAL MANIFESTATIONS

Heterozygous carriers are usually asymptomatic, but homozygotes have lifelong bleeding that typically starts shortly after birth with persistent bleeding around the umbilical stump. Intracranial bleeding events, usually precipitated by minimal trauma, occur commonly enough in infants (25%) to justify the initiation of a primary prophylaxis regimen of replacement therapy. Delayed bleeding after surgery and trauma is the hallmark of the disease. However, easy bruising, poor wound healing with defective scar formation and dehiscence, and hemarthroses are also characteristic. Spontaneous abortions are increased in severely affected women.

DIAGNOSIS

The diagnosis is usually suspected on clinical grounds, given that factor XIII deficiency is not detected by conventional screening coagulation tests (i.e., aPTT, PT). Most laboratories use a rapid screening assay that assesses the ability of a fibrin clot to remain intact with incubation in 5 mol/L of urea or 1% monochloroacetic acid. With factor XIII levels less than 1% of normal, the clot dissolves within 2 to 3 hours. However, the clot solubility tests are not standardized and have a low sensitivity.[25]

TREATMENT

Normal hemostasis is achieved with a factor XIII level of only 5% of normal. Replacement therapy for prophylaxis or the treatment of acute bleeds in factor XIII deficiency can be accomplished by administering plasma-derived factor XIII concentrate, which is pasteurized for viral safety, or fresh frozen plasma. Recombinant factor XIII is safe and effective in preventing bleeds in factor XIII–deficient patients. The dose is 10 to 20 U/kg intravenously given every 3 to 4 weeks. Acquired alloantibody inhibitors can develop in severely affected individuals. Autoantibodies also occur, usually in association with systemic lupus erythematosus.

DYSFIBRINOGENEMIA AND AFIBRINOGENEMIA

Approximately 300 abnormal fibrinogens have been described, but few cause hemostatic symptoms. Abnormal fibrinogens are rare, autosomally inherited proteins. Quantitative fibrinogen deficiencies (afibrinogenemia and hypofibrinogenemia) may result from mutations affecting fibrinogen synthesis or processing, whereas qualitative defects (dysfibrinogenemia) are caused by mutations that lead to abnormal polymerization, defective cross-linking, or defective assembly of the fibrinolytic system.

The prevalence of dysfibrinogenemia in patients with a history of thromboembolic episodes approaches 0.8%. A high prevalence of dysfibrinogenemia has been reported among patients with chronic thromboembolic hypertension, thereby implicating changes in the molecular structure of fibrin in the development of this disorder. Clinically insignificant dysfibrinogenemias may be acquired in association with hepatocellular carcinoma.

CLINICAL MANIFESTATIONS

More than 50% of the dysfibrinogenemias are asymptomatic, 25% are associated with a mild hemorrhagic tendency (commonly caused by defective release of fibrinopeptide A), and 20% predispose individuals to thrombosis (usually caused by impaired fibrinolysis; Chapter 67). Concurrent bleeding and thrombosis also may occur. Women experience a high incidence of pregnancy-related complications, such as spontaneous abortion and postpartum thromboembolic events. Thrombin times and reptilase times (plasma-based clotting times with the substitution of reptilase snake venom for thrombin) are not helpful in predicting whether an abnormal fibrinogen will be prothrombotic, prohemorrhagic, or asymptomatic. However, clinical history, fibrinopeptide release studies, and fibrin polymerization studies may be useful.

In contrast to the hepatic synthesis of a qualitatively abnormal protein in dysfibrinogenemia, congenital afibrinogenemia is an autosomal recessive disorder that causes markedly deficient production of the normal protein. Severe life-threatening hemorrhagic complications can occur at any site, beginning at birth with umbilical bleeding. Intracranial hemorrhage is a frequent cause of death. Poor wound healing is characteristic.

DIAGNOSIS

Abnormalities are usually detected incidentally when routine coagulation screening assays reveal decreased fibrinogen concentrations and prolonged thrombin clotting times. On further evaluation, discordance between functional and immunologic fibrinogen levels (>50 mg/dL more antigenic than functional) is observed; clotting times using snake venom (reptilase or ancrod) are variably prolonged.

Afibrinogenemia is usually detectable by specific functional or immunologic assays. Platelet dysfunction may accompany afibrinogenemia and exacerbate bleeding.

TREATMENT

Deficiencies of fibrinogen can be corrected by the administration of cryoprecipitate or a viral-attenuated (pasteurized), plasma-derived fibrinogen concentrate.[26] The target replacement goal is 100 mg/dL, and given a circulating biologic half-life of at least 96 hours, treatment every 3 to 4 days is adequate.

Thrombosis is a potential complication of treatment. Primary prophylaxis regimens may be useful in afibrinogenemia, with on-demand or prophylactic replacement for trauma or surgery. Fibrinogen replacement may reduce not only bleeding but also thrombosis. Individuals with thrombophilic manifestations should receive anticoagulation long-term, depending on risk-benefit assessment. Solvent/detergent plasma, which is a pooled human plasma that reduces allergic reactions and transfusion-related acute lung injury, or psoralen-treated fresh frozen plasma may be alternatives.

FACTOR V DEFICIENCY

Factor V is a component of the prothrombinase complex that assembles factors Va and Xa on the phospholipid membrane of the platelet for prothrombin (factor II) activation to thrombin.

CONGENITAL FACTOR V DEFICIENCY

Deficiency of factor V is a rare, autosomal recessive disorder (1 in 1 million births). The factor V Leiden protein, which is responsible for resistance to activated protein C and thrombophilia, does not affect factor V coagulant activity. The severity of plasma factor V deficiency correlates less well with the risk of clinical bleeding than does the factor V content in platelet α-granules. This observation illustrates the critical role of the platelet in promoting adequate hemostasis at bleeding sites and explains why transfusions of normal platelets may be preferred over fresh frozen plasma for the treatment of hemorrhagic episodes secondary to congenital or acquired factor V deficiency. Hemostasis can be maintained without correcting plasma factor V activity (>25% of normal). Recombinant factor VIIa has also been used off-label to treat bleeding in factor V deficiency.

COMBINED DEFICIENCIES OF FACTORS V AND VIII

Factors V and VIII are structurally homologous proteins, and combined deficiencies of these factors occur as an autosomal recessive disorder with a prevalence of 1 in 100,000 births among Jews of Sephardic origin. The disorder is believed to be caused by defective secretion due to mutations in export proteins in the endoplasmic reticulum of endothelial cells. The severity of bleeding is determined by the levels of these factors, which usually range from 5 to 30% of normal. Replacement therapy should be aimed at normalizing both clotting protein activities.

ACQUIRED FACTOR V DEFICIENCY

Acquired factor V deficiency has been described in individuals exposed to bovine factor V, which contaminates the thrombin preparations used topically to control bleeding during cardiovascular surgery. This abnormality probably represents the development of anti–bovine factor V antibodies that cross-react with the human factor V protein. Profuse bleeding accompanies this complication.

DEFICIENCIES OF VITAMIN K–DEPENDENT COAGULATION

DEFICIENCIES OF FACTORS II, VII, AND X

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Congenital deficiencies of factors II (prothrombin), VII, and X are rare, autosomally inherited disorders. Heterozygotes (with factor levels approximately 20% of normal) are typically asymptomatic except in the immediate newborn period, when physiologic vitamin K deficiency exacerbates the underlying clotting factor deficiency. Homozygotes with clotting factor levels less than 10% of normal manifest variable symptoms. As with other coagulopathies, these deficiencies are usually suspected after neonatal umbilical stump bleeding. Thereafter, unless replacement or prophylactic therapy is provided, these patients are subject to mucosal bleeding from epistaxis, menorrhagia, and dental extractions; hemarthroses and intramuscular hematomas; and bleeding after surgery or trauma.

Acquired factor VII deficiency has been associated with Dubin-Johnson and Gilbert syndromes (Chapter 133). Acquired factor IX deficiency has been associated with Gaucher disease, because factor IX binds to glucocerebroside. Acquired factor X deficiency and amyloidosis are discussed later.

DIAGNOSIS

In the coagulation laboratory, factor VII deficiency is associated with a prolonged PT and a normal aPTT. This pattern localizes the deficiency to the extrinsic pathway. In contrast, deficiencies of factors II (prothrombin) and X prolong both the PT and the aPTT, with the defects localized to the common pathway of coagulation. A Russell viper venom–based clotting test can differentiate between these two deficiencies; as a direct activator of factor X, the assay is prolonged with factor X deficiency but not with factor II deficiency. Mixing patient plasma with normal plasma results in a correction of these assays, and specific clotting assays using plasma deficient in the coagulation protein to be studied can confirm the diagnosis.

TREATMENT

Replacement therapy is indicated for acute symptomatic bleeds and for prophylaxis before surgery. Plasma-derived factor X is available to treat bleeding in factor X deficiency. Alternatively, factor IX complex concentrates can be administered to achieve hemostatic levels of any of these vitamin K–dependent factors (25 to 30% of normal).

Bleeding complications caused by acquired IgG autoantibodies directed against any coagulation factor protein can be reversed rapidly, albeit temporarily, by extracorporeal immunoadsorption over a Sepharose-bound polyclonal antihuman IgG or staphylococcal A column, with concomitant replacement therapy and initiation of immunosuppression. Recombinant factor VIIa is increasingly used for surgery in patients with rare congenital coagulation deficiencies and Glanzmann thrombasthenia, but typically at lower doses than with hemophilia inhibitors—generally 10 to 15 μg/kg per dose for up to several days.

FACTOR DEFICIENCY IN AMYLOIDOSIS

Severe acquired deficiency of factor X, often accompanied by deficiencies of other vitamin K–dependent factors, occasionally occurs in individuals with systemic amyloidosis (Chapter 174). Because amyloid fibrils in the reticuloendothelial system bind endogenous and exogenous sources of factor X, replacement therapy with FFP or factor IX complex concentrates, even in large quantities, may not be sufficient. Recombinant factor VIIa concentrate has been used to reverse acute bleeding. Splenectomy may ameliorate recurrent bleeding complications.

OTHER ACQUIRED COAGULATION ABNORMALITIES

ANTIPHOSPHOLIPID SYNDROME AND LUPUS ANTICOAGULANT

EPIDEMIOLOGY

The antiphospholipid antibody syndrome is associated with recurrent thrombosis or recurrent pregnancy loss with autoantibodies directed against phospholipids. Antiphospholipid antibodies may include lupus anticoagulant, anticardiolipin antibody (CL), or anti-β2-glycoprotein-I (anti-β2-GPI). Thrombocytopenia is also a common finding in this prothrombotic disorder. Rarely, multiorgan failure may arise from widespread thrombosis, a syndrome called catastrophic antiphospholipid antibody syndrome.

PATHOBIOLOGY

The prothrombotic effects of antiphospholipid antibodies may derive from their ability to complex with β2-GPI in vivo (thereby negating their modulatory phospholipid-binding function) or through inhibition of protein C activation, interference with antithrombin III activity, and/or disruption of the annexin V shield, thereby preventing normal clot breakdown (fibrinolysis). Although complement and inflammation play a role in fetal loss in a murine model of antiphospholipid antibody syndrome, the pathogenic mechanism of pregnancy loss remains unclear. Although non–β2-GPI antibodies detected by CL enzyme-linked immunosorbent assay (ELISA) may play a role in early obstetric antiphospholipid antibody syndrome, and anti-β2-GPI antibodies with lupus anticoagulant activity play a role in late miscarriage, additional studies are needed to classify, understand, and manage this syndrome.

CLINICAL MANIFESTATIONS

Lupus anticoagulants prolong coagulation in in vitro assays but are not generally associated with clinical bleeding. Rarely, clinical bleeding may occur when antiphospholipid antibody antibodies interact with factor II (prothrombin), producing an acquired prothrombin (factor II) deficiency associated with accelerated clearance of lupus anticoagulant–prothrombin complexes from the circulation. Bleeding tendencies also may arise when the lupus anticoagulant targets platelet membranes and produces quantitative or qualitative platelet abnormalities. Other clinical findings in the antiphospholipid antibody syndrome include livedo reticularis, valvular heart lesions, and nephropathy. Clinically, although both arterial and venous thrombosis may occur in the antiphospholipid antibody syndrome, the most relevant is venous thrombosis and stroke in young adults. A diagnostic evaluation in those with arterial thrombosis should include transesophageal echocardiography to exclude a cardiac source for arterial clots. In obstetric patients, other causes of miscarriage should be excluded. A history of recurrent spontaneous abortion associated with antiphospholipid antibody syndrome is a risk factor for subsequent venous thromboembolism in the long term. Nonpregnant individuals with antiphospholipid antibody syndrome–associated thrombotic manifestations have a 50% risk of experiencing recurrent events over a 5-year period. Typically, recurrent thrombotic episodes occur in a pattern consistent with the initial findings (e.g., venous recurrence following an initial deep vein thrombosis).[27]

DIAGNOSIS

The diagnosis of antiphospholipid antibody syndrome is based on both clinical and laboratory criteria. Clinical criteria include arterial, venous, or small-vessel thrombosis in any tissue or organ and pregnancy morbidity.[28] The latter includes one or more pregnancy losses before 10 weeks' gestation; one or more pregnancy losses before 34 weeks due to eclampsia, preeclampsia, or placental insufficiency; or three or more spontaneous abortions before 10 weeks. Antiphospholipid antibody syndrome may be suspected in the setting of recurrent spontaneous miscarriages or pregnancy-related thromboembolic events, with the detection of cerebral arterial thromboses in young adults, in those with systemic lupus erythematosus (20 to 40%; Chapter 245) or other autoimmune diseases or lymphoproliferative malignancies, in those receiving psychotropic medications (e.g., chlorpromazine), or when incidental coagulation assays reveal aPTT prolongation.

Laboratory criteria for antiphospholipid antibody syndrome include the detection of one or more high-titer antiphospholipid antibodies (lupus anticoagulant, CL, anti-β2-GPI) on at least two occasions at least 12 weeks apart. Antiphospholipid antibodies can be detected by three assays: the lupus anticoagulant assay, the CL ELISA assay, and the β2-GPI ELISA assay. The lupus anticoagulant assay includes a screening test, based on a prolonged phospholipid-dependent clotting time; a mixing test that distinguishes the inhibitor (fails to correct in a 1 : 1 mix) from a deficiency state (corrects in a 1 : 1 mix); and a confirmatory test based on platelet neutralization to demonstrate that the inhibitor is phospholipid dependent (clotting time corrects) or a modified aPTT reagent based on the binding of hexagonal-phase phospholipids to lupus anticoagulants. The CL ELISA measures antibodies in dilute sera that bind to CL-coated plates, including those that bind to CL alone or bound to bovine β2-GPI and both IgG and IgM, but it may miss CL bound to human β2-GPI. The β2-GPI ELISA detects antibodies that bind to β2-GPI–coated irradiated plates, but it has reduced specificity owing to binding by nonpathogenic antibodies. Positivity in multiple assays is strongly associated with thrombosis and miscarriage. The risk of first thrombosis among asymptomatic individuals positive for lupus anticoagulants, CL, and β2-GPI antibodies, so-called triple-positive patients, is about 5% per year. Of the three assays, the β2-GPI ELISA is most strongly associated with thrombosis and early recurrent miscarriage; the lupus anticoagulant assay is associated with venous thrombosis, stroke, and late miscarriage. The greatest weight is given to a positive lupus anticoagulant test. From a practical standpoint, testing for all three antibodies at diagnosis is recommended to guide follow-up, because oral anticoagulants may interfere with the lupus anticoagulant test.

TREATMENT

Because of the high risk of recurrent thromboembolism, patients with the antiphospholipid antibody syndrome should receive antithrombotic therapy. The approach is based on achieving a balance between thrombosis risk and bleeding complications, especially in those with thrombocytopenia. Recommendations for patients who have the antiphospholipid antibody syndrome emphasize the use of unfractionated heparin or low-molecular-weight heparin (LMWH), with a 4- to 5-day overlap with warfarin, for acute venous thromboembolism, followed by long-term warfarin to a target international normalized ratio (INR) of 2.0 to 3.0. In individuals with thrombocytopenia, more frequent monitoring of the INR may be warranted to avoid bleeding complications. The direct oral anticoagulant rivaroxaban, although effective in prevention of venous thrombosis, is not as effective as warfarin for arterial thrombosis,[A7] so warfarin remains the treatment of choice in patients who have the antiphospholipid antibody syndrome. The duration of anticoagulation is based on a balance between the risks of bleeding compared with the risks of recurrent thrombosis.

For women with the antiphospholipid antibody syndrome and a prior pregnancy loss but no past thrombosis, the goal is to prevent recurrent pregnancy loss. Based on randomized trials, recommendations generally include low-dose aspirin (81 mg daily) in combination with prophylactic heparin or LMWH in the antepartum period.[29,30]

In the setting of bleeding or when the inherent risk of bleeding exceeds the risk of bleeding with treatment among patients with antiphospholipid antibody syndrome–associated thrombocytopenia and a platelet count below 20,000 to 30,000/μL, management is similar to that for idiopathic thrombocytopenic purpura (see Chapter 158). Case reports indicate that danazol, dapsone, aspirin, or chloroquine may be helpful adjuncts under expert supervision. In pregnant women with antiphospholipid antibody syndrome–associated thrombocytopenia, treatment is advised before epidural anesthesia or cesarean section. In the latter case, early delivery under cover of intravenous immunoglobulin is recommended.

Treatment of antiphospholipid antibody syndrome–associated bleeding is dependent on the site and severity of bleeding. For patients who are taking anticoagulant therapy, the anticoagulant should be withheld and an antidote (e.g., protamine or vitamin K) should be given. For thrombocytopenic bleeding, platelet transfusions should be administered, with red blood cell transfusions if necessary. If both thrombosis and bleeding occur, treatment should be directed at the component that is most life-threatening. In patients with a high bleeding risk, anticoagulants should be withheld or given at a lower dosage; patients with a high thrombotic risk despite thrombocytopenia should be anticoagulated and given agents to boost the platelet count.

In the life-threatening multisystem complication of catastrophic antiphospholipid syndrome, which is characterized by histopathologic evidence of small vessel thrombosis and dysfunction of multiple organs (e.g., lung, brain, heart, kidneys, skin, or gastrointestinal tract) over a short period of time, maximal anticoagulation, plasma exchange, and immunosuppressive therapy have been used under expert supervision. Eculizumab, an inhibitor of terminal complement, was effective in a patient with recurrent catastrophic antiphospholipid syndrome.

161 DISSEMINATED INTRAVASCULAR COAGULATION AND BLEEDING IN LIVER FAILURE

ANDREW I. SCHAFER

DISSEMINATED INTRAVASCULAR COAGULATION

DEFINITION

Disseminated intravascular coagulation (DIC), also referred to as consumptive coagulopathy or defibrination, is caused by a wide variety of serious disorders (Table 161-1). In most patients, the underlying process dominates the clinical picture, but in some cases (e.g., occult malignant neoplasm, envenomation), DIC may be the initial or predominant manifestation of the disorder. DIC never occurs in isolation, without an inciting cause.

PATHOBIOLOGY

DIC is primarily a thrombotic process from a pathophysiologic perspective. However, its clinical manifestation may appear to be widespread hemorrhage in acute cases. The basic pathophysiologic mechanism (Fig. 161-1), regardless of cause, is entry into the circulation of procoagulant substances that trigger systemic activation of the coagulation system and platelets.[1] This results in disseminated deposition of fibrin-platelet thrombi within the microvasculature. In most cases, the procoagulant stimulus is tissue factor, a lipoprotein that is not normally exposed to blood. In DIC, tissue factor gains access to blood by tissue injury, its elaboration by malignant cells, or its expression on the surface of monocytes and endothelial cells by inflammatory mediators. Components of the inflammatory response and the coagulation system are reciprocally activated in some forms of DIC, such as sepsis. Tissue factor triggers generation of the coagulation protease thrombin, which induces fibrin formation and platelet activation. In some specific cases of DIC, procoagulants other than tissue factor (e.g., a cysteine protease or mucin in certain malignant neoplasms) and proteases other than thrombin (e.g., trypsin in pancreatitis, exogenous enzymes in envenomation) provide the procoagulant stimulus.

In acute, uncompensated DIC, coagulation factors are consumed at a rate in excess of the capacity of the liver to synthesize them, and platelets are consumed in excess of the capacity of bone marrow megakaryocytes to release them. The resulting laboratory manifestations under these circumstances are a prolonged prothrombin time (PT), a prolonged activated partial thromboplastin time (aPTT), and thrombocytopenia. Increased fibrin formation in DIC stimulates a heightened process of secondary fibrinolysis, in which plasminogen activators generate plasmin to digest fibrin (and fibrinogen) into fibrin(ogen) degradation products (FDPs). FDPs are potent circulating anticoagulants that further contribute to the bleeding manifestations of DIC. Intravascular fibrin deposition can cause fragmentation of red blood cells and lead to the appearance of schistocytes in blood smears (see Chapter 143); however, frank microangiopathic hemolytic anemia is unusual in DIC. Occlusive microvascular thrombosis in DIC can compromise the blood supply to some organs and lead to multiorgan failure, particularly when it is accompanied by systemic hemodynamic, inflammatory, and metabolic derangements.

TABLE 161-1 MAJOR CAUSES OF DISSEMINATED INTRAVASCULAR COAGULATION

INFECTIONS
Gram-negative bacterial sepsis
Other bacteria, fungi, viruses, Rocky Mountain spotted fever, malaria
IMMUNOLOGIC REACTIONS
Transfusion reactions (ABO incompatibility)
Organ transplant rejection
Hematopoietic stem cell transplantation
Chimeric antigen receptor (CAR) T-cell therapy
OBSTETRIC COMPLICATIONS
Amniotic fluid embolism
Retained dead fetus
Abruptio placentae
Toxemia, preeclampsia
Septic abortion
MALIGNANT NEOPLASMS
Pancreatic carcinoma
Adenocarcinomas
Acute promyelocytic leukemia
Other neoplasms
LIVER FAILURE
ACUTE PANCREATITIS
ENVENOMATION
RESPIRATORY DISTRESS SYNDROME
TRAUMA, SHOCK
Brain injury
Crush injury
Burns
Hypothermia or hyperthermia
Fat embolism
Hypoxia, ischemia
Surgery
VASCULAR DISORDERS
Giant hemangioma (Kasabach-Merritt syndrome)
Aortic aneurysm
Vascular tumors or malformations

Underlying Causes

DIC always has an underlying cause that must be identified and eliminated if the coagulopathy is to be managed successfully. The development of DIC in some of these disorders is associated with an unfavorable outcome. Infection is the most common cause of DIC. The syndrome is particularly associated with gram-negative or gram-positive sepsis (Chapter 94),[2] although it can be triggered by a variety of other bacterial, fungal, viral, rickettsial, and protozoal microorganisms. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) with coronavirus disease 2019 (COVID-19) infection (Chapter 336) can also be associated with a picture of DIC.[3]

The placenta and uterine contents are rich sources of tissue factor and other procoagulants that are normally excluded from the maternal circulation; a spectrum of clinical manifestations of DIC may accompany obstetric complications when this barrier is breached, especially in the third trimester. These syndromes range from acute, fulminant, and often fatal DIC in amniotic fluid embolism to chronic or subacute DIC with a retained dead fetus. Other obstetric problems associated with DIC include abruptio placentae, toxemia, and septic abortion.

Chronic forms of DIC are caused by a variety of malignant neoplasms, particularly acute myeloid leukemia,[4] pancreatic cancer (Chapter 180), and mucin-secreting adenocarcinomas of the gastrointestinal tract (Chapter 179), in which thrombotic rather than bleeding manifestations predominate. Treatment with all-*trans*-retinoic acid has greatly reduced the incidence of severe DIC in patients with acute promyelocytic leukemia (Chapter 168). Up to 50% of patients develop coagulopathy following chimeric antigen receptor (CAR) T-cell therapy, often in the form of DIC. Likewise, coagulopathy with features of DIC can develop with hematopoietic stem cell transplantation (Chapter 163). It is not known whether liver failure (see later) can cause DIC or whether its coexistence merely exacerbates intravascular coagulation because of impaired clearance of activated clotting factors, plasmin, and FDPs. Snake venom contains a variety of substances that can affect coagulation and endothelial permeability. Bites from rattlesnakes and other vipers can induce profound DIC by introduction of these exogenous toxins and release of endogenous tissue factor through tissue necrosis.

The likelihood and degree of DIC caused by trauma, surgery, and shock (Chapter 92) are related to the extent of tissue damage and the organs involved. The brain is a particularly rich source of tissue factor, so traumatic brain injury (Chapter 368) can precipitate acute DIC.[5] Large aortic aneurysms (Chapter 63), giant hemangiomas, and other vascular malformations can cause subclinical or clinical chronic DIC that is initiated locally within the abnormal vasculature but can spill into the systemic circulation.[6]

CLINICAL MANIFESTATIONS

The clinical manifestations of DIC are determined by the nature, intensity, and duration of the underlying stimulus. The coexistence of liver disease

ABSTRACT

Mixed hemorrhagic disorders that involve deficiencies in multiple coagulation factors as well as platelets include disseminated intravascular coagulation (DIC) and the coagulopathy of liver failure. Vitamin K deficiency causes deficiencies of specific vitamin K–dependent coagulation factors II (prothrombin), VII, IX, and X, as well as specific vitamin K–dependent prothrombotic factors protein C and protein S, but does not involve platelets. DIC, also called consumptive coagulopathy, is a syndrome caused by a wide variety of disorders that all have in common their activation of the clotting system at different points in the coagulation cascade, leading to increased fibrin deposition in the microvasculature. So DIC is primarily a thrombotic disorder and may in fact present in its chronic form as thrombosis or occlusive organ dysfunction. The bleeding that more typically accompanies DIC, especially in acute cases, results from consumption of all clotting factors, consumption of platelets, and activation of the fibrinolytic system. The coagulopathy of liver failure is likewise a complex disorder that has both prothrombotic and antithrombotic components. Therefore, while most patients with liver failure have a bleeding diathesis, thrombosis can also occur depending on the balance of these opposing forces. Complete resolution of the coagulopathy of DIC and liver failure, which often coexist, depends on the ability to control the underlying disease.

KEYWORDS

disseminated intravascular coagulation

exacerbates DIC of any cause. Low-grade DIC is often asymptomatic and diagnosed only by laboratory abnormalities. Thrombotic complications of DIC occur most often with chronic underlying diseases, as exemplified by Trousseau syndrome in cancer (Chapter 67). The thrombotic phenotype of DIC, which occurs prototypically in association with solid tumor malignancies, can manifest as large vessel venous or arterial thrombosis, or as ischemic organ dysfunction due to microvascular thrombosis, or even as a thrombotic microangiopathy. DIC can present as acrocyanosis and gangrene of the digits in critically ill, hemodynamically compromised patients receiving vasopressors. Hemorrhagic necrosis of the skin (Fig. 161-2) and purpura fulminans may also be manifestations of DIC. Bleeding is the most common clinical finding in acute, uncompensated DIC. Bleeding can be limited to sites of intervention or anatomic abnormalities, but it tends to be generalized in more severe cases, including widespread ecchymoses and diffuse oozing from mucosal surfaces and orifices. In these cases, causes of which are exemplified by major trauma, abruptio placentae, or acute promyelocytic leukemia, the precipitating trigger is also a prothrombotic activation of the coagulation system but a fulminant, uncontrolled fibrinolytic response creates a bleeding or so-called fibrinolytic phenotype.

DIAGNOSIS

The laboratory diagnosis of fulminant acute DIC is not usually difficult.[7] Consumption and inhibition of the function of clotting factors cause prolongation of the PT, aPTT, and thrombin time. Consumption of platelets causes thrombocytopenia. Secondary fibrinolysis generates increased titers of FDPs, which can be measured by latex agglutination or D-dimer assays. Some schistocytes may be seen in the peripheral blood smear, but this finding is neither sensitive nor specific for DIC. Chronic or compensated forms of DIC are more difficult to diagnose, with highly variable patterns of abnormalities in "DIC screen" coagulation tests. Increased D-dimers and a prolonged PT are generally more sensitive measures than are abnormalities of the aPTT and platelet count. Overcompensated synthesis of consumed clotting factors and platelets in some chronic forms of DIC may actually cause shortening of the PT and aPTT or thrombocytosis (or both), even though elevated levels of D-dimers indicate secondary fibrinolysis in such cases. Elevated circulating D-dimers are nonspecific, but normal levels have a high negative predictive value for DIC.[8]

The most difficult differential diagnosis of DIC occurs in patients who have coexisting liver disease. The coagulopathy of liver failure (see the later section on liver failure) is often indistinguishable from that of DIC, partly because advanced hepatic dysfunction is in fact accompanied by a state of DIC. In liver failure, the combination of decreased synthesis of clotting factors, impaired clearance of activated clotting factors, secondary fibrinolysis, and thrombocytopenia from portal hypertension and hypersplenism may make the coagulopathy virtually impossible to differentiate from DIC. The coagulopathy associated with postpartum hemorrhage is rarely caused by DIC alone; there may also be varying proportions of dilutional coagulopathy, localized consumption, and increased fibrinolysis. Thrombotic microangiopathies including thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome, the syndrome of "hemolysis, elevated liver enzymes, and low platelet count" (HELLP) in obstetric patients, and other forms of platelet consumption and thrombocytopenia (Chapter 158) are not accompanied by activation of clotting factors or secondary fibrinolysis; therefore, the PT, aPTT, thrombin time, and D-dimers are generally normal in these disorders. Schistocytes, often with frank hemolysis, are much more prominent in the peripheral smear in thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome (Chapter 158) than in DIC. One situation where DIC and thrombotic microangiopathy can overlap and even coexist is in patients with cancer-associated thrombotic microangiopathy. These patients typically have bone marrow involvement and systemic microvascular metastases, either in the setting of known metastatic cancer or unexpectedly on presentation.

TREATMENT

Successful treatment of DIC (Table 161-2) requires that the underlying cause be identified and eliminated. All other therapies, including hemodynamic support, replacement of coagulation factors and platelets, and pharmacologic inhibitors of coagulation and fibrinolysis, are just temporizing measures. Because of the difficulty of testing this complex syndrome with multiple causes by controlled, randomized clinical trials, current guidelines for treatment are generally not based on high-grade evidence.[9]

In many patients with asymptomatic, self-limited DIC who have only laboratory manifestations of the coagulopathy, no treatment may be necessary. In patients with DIC who are actively bleeding or who are at high risk for bleeding, the blood component treatments of choice are transfusions of platelets to improve the thrombocytopenia and fresh-frozen plasma to replace all consumed coagulation factors and to correct the prolonged PT and aPTT. In the absence of robust evidence-based guidelines for the treatment of DIC, an

TABLE 161-2 TREATMENT OF DISSEMINATED INTRAVASCULAR COAGULATION

Identify and eliminate the underlying cause
No treatment if mild, asymptomatic, and self-limited
Hemodynamic support, as indicated, in severe cases
Blood component therapy
Indications: active bleeding or high risk for bleeding
Fresh-frozen plasma
Platelets
In some cases, consider cryoprecipitate, antithrombin III
Drug therapy
Indications: heparin for DIC manifested by thrombosis or acrocyanosis and without active bleeding; antifibrinolytic agents are generally contraindicated except with life-threatening bleeding and failure of blood component therapy

DIC = disseminated intravascular coagulation.

international consensus group recommended VTE prophylaxis in critically ill DIC patients, switching from pharmacologic to mechanical prophylaxis in the case of bleeding and maintaining platelets at greater than 20,000. For some patients who have particularly profound hypofibrinogenemia, the additional transfusion of cryoprecipitate, a plasma concentrate that is enriched in fibrinogen, may be useful. The theoretical concern that these blood products could "fuel the fire" and exacerbate the DIC has not been supported by clinical experience.

The use of pharmacologic inhibitors of coagulation and fibrinolysis in DIC is controversial. Heparin is of theoretical benefit because it blocks thrombin activity and quenches intravascular coagulation and the resultant secondary fibrinolysis. In practice, heparin might exacerbate the bleeding tendency in acute DIC. Heparin is usually reserved for special forms of DIC, including those manifested by thrombosis or acrocyanosis and forms that accompany cancer, vascular malformations, retained dead fetus, and possibly acute promyelocytic leukemia, in which active bleeding is not present. A meta-analysis of randomized controlled trials of anticoagulant therapy specifically in patients with sepsis and sepsis-induced DIC showed an increased risk of bleeding but significant reduction in mortality only in patients who had DIC.[A1] In cases of DIC in which thrombosis or acral ischemia predominates, unfractionated heparin should be used by continuous infusion because of its short half-life and reversibility in the event of increased bleeding. Monitoring the aPTT in the presence of DIC may be problematic, so heparin infusion in this setting should be followed mainly by clinical response and improvement in results of other tests of coagulation (e.g., thrombocytopenia). Antifibrinolytic agents, including ε-aminocaproic acid and tranexamic acid, are generally contraindicated in DIC. By blocking the secondary fibrinolytic response to DIC, these drugs cause unopposed fibrin deposition and may precipitate thrombosis. Antifibrinolytic agents may be effective in decreasing life-threatening bleeding in DIC, however, particularly in extreme cases in which aggressive blood component replacement fails to control the hemorrhage; in such situations, simultaneous infusion of low doses of heparin is needed to reduce the risk for thrombosis.

Antithrombin III and recombinant human soluble thrombomodulin[10] may have some efficacy in improving laboratory parameters of DIC, but neither reduces mortality significantly. Specific surgical treatments and pharmacotherapy may be required for treatment of DIC in patients with aortic aneurysm or vascular malformations.

LIVER FAILURE

Bleeding complications in patients with advanced liver disease (Chapters 139 and 140) can be severe and even fatal and directly account for about 20% of the deaths associated with hepatic failure. Procoagulant abnormalities often coexist. The extent of the bleeding tendency depends on the severity and type of liver disease involved. However, the hemostatic profile in liver failure is unrelated to the Model for End-stage Liver Disease (MELD) score (Table 139-2).[11] About one third of deaths in patients undergoing liver transplantation are attributable to perioperative hemorrhage.

PATHOBIOLOGY

The pathophysiologic mechanism of bleeding in liver failure is multifactorial. The complexity of the systemic coagulopathy of hepatic disease is not surprising inasmuch as the liver is the principal organ site for the synthesis of almost all the coagulation and fibrinolytic factors as well as their inhibitors. (Hepatocytes synthesize all the clotting factors except for von Willebrand factor [vWF], which serves as a physiologic "carrier" and stabilizer of factor VIII, so the elevated levels of vWF that are seen in liver disease can enable near-normal circulating levels of factor VIII despite diminished synthesis of the latter.) Thus, the abnormal hemostasis of liver failure is accompanied by opposing antithrombotic and prothrombotic alterations. Unfortunately, currently available laboratory tests of coagulation, with the possible future exception of thromboelastography (Chapter 157), cannot measure the net effect of the complex, incongruous hemostatic forces that are at work at any given time on clinical bleeding or thrombotic risk in a patient with liver disease. For example, the PT/international normalized ratio (INR) is still accepted as a valid prognostic marker of liver failure, but can no longer be considered a reliable indicator of bleeding tendency in these patients. Although the degree of prolongation of the PT/INR was commonly used in the past to guide treatment with fresh-frozen plasma (FFP) or prothrombin complex concentrate (PCC), it is now recognized that it is not a useful predictor of bleeding after surgery or an invasive procedure. This explains why having certain prolongations of the PT/INR and aPTT as a function of liver disease cannot be regarded as being functionally "auto-anticoagulated"; this notion is a seriously misleading fallacy.

The opposing hemostatic forces at work due to liver failure include (1) decreased *total* levels of circulating clotting factors (caused by consumption of the factors), (2) hypo- or dysfibrinogenemia, (3) enhanced fibrinolysis, and (4) increased levels of fibrin degradation products that act as circulating anticoagulants. All these forces promote bleeding, with simultaneously (1) increased levels of *activated* clotting factors (caused by impaired hepatic clearance), (2) decreased levels of the physiologic anticoagulant proteins antithrombin III (AT III), protein C and protein S (caused by consumption of those proteins), (3) elevated levels of von Willebrand factor and factor VIII, and (4) low plasminogen, all promoting thrombosis. Two factors that may tip the balance more toward a bleeding than a thrombotic phenotype in most of these patients are thrombocytopenia and anatomically vulnerable sites of bleeding in the GI tract, such as esophageal and gastric varices, gastritis (congestive gastropathy), and hemorrhoids.

There is an increased incidence of deep vein thrombosis and/or pulmonary embolism in patients with chronic liver disease (ranging from 0.5 to 6% in different studies). There is an even higher risk of portal vein thrombosis (ranging from 7 to 18% in different series; Chapter 129).[12]

Quantitative and qualitative abnormalities of platelets also contribute to the bleeding diathesis of liver failure. Congestive splenomegaly secondary to portal hypertension causes increased pooling of platelets in the spleen (hypersplenism). The resultant thrombocytopenia, the degree of which generally correlates with spleen size, rarely causes a reduction in the platelet count to less than 30,000/μL. In alcoholic patients, suppression of bone marrow thrombopoiesis by the acute toxic effects of alcohol or folate deficiency may contribute to the thrombocytopenia. Qualitative platelet abnormalities have also been described in patients with liver disease.

Liver transplantation (Chapter 140) poses special problems to the coagulation system. During the 2-hour or so anhepatic stage of surgery, defined as the time from physical removal of the liver from the recipient to recirculation of the graft, the complete cessation of synthesis of coagulation factors causes further prolongation of the PT and aPTT. Release of tissue plasminogen activator from the newly grafted liver leads to increased fibrinolysis and transient exacerbation of bleeding risk in the postoperative period.

CLINICAL MANIFESTATIONS

The most common hemorrhagic complication of liver disease is gastrointestinal bleeding, which is usually caused by anatomic abnormalities and exacerbated by the systemic coagulopathy of liver failure. Bleeding from other mucosal sites, extensive ecchymoses, or more serious hemorrhage into the retroperitoneum or central nervous system generally indicates more significant derangements of the coagulation system.

The severe coagulopathy in patients with liver disease makes liver biopsy a potentially hazardous procedure. The PT and platelet count may be the best guides to bleeding risk, but they lack reliability as predictors of risk of bleeding with liver biopsy. In general, liver biopsy can be performed safely if the platelet count is higher than 50,000/μL. The American Association for the Study of Liver Diseases has concluded that the bleeding risk-benefit ratio of liver biopsy must be carefully considered on a case-by-case basis.

DIAGNOSIS

Although the PT and aPTT are often prolonged in patients with advanced liver disease, the PT tends to be a more sensitive assay early in the course; a disproportionate prolongation of the aPTT should raise suspicion of a coexisting coagulation abnormality, such as a lupus anticoagulant or clotting factor inhibitor. A prolonged PT is also a useful prognostic indicator of poor outcome in patients with cirrhosis, acute acetaminophen hepatotoxicity, and acute viral

hepatitis; in acute viral hepatitis, it is a better index of prognosis than are serum albumin and transaminases. A disproportionate prolongation of the thrombin time should suggest the presence of dysfibrinogenemia. Hypersplenism (Chapter 154), possibly associated with nutritional folate deficiency or the acute toxic effects of alcohol on bone marrow, often causes mild to moderate thrombocytopenia in patients with liver disease. Thrombocytopenia in liver disease can also be due to impaired synthesis of thrombopoietin, the primary megakaryocytopoietic growth factor (Chapter 142). However, consideration should be given to other coexisting causes of thrombocytopenia if the platelet count is significantly less than 30,000/μL.

The coagulopathy of liver failure is often indistinguishable from that of DIC, in part because some degree of DIC is in fact a necessary accompaniment of advanced liver disease. In general, patients with DIC have more marked decreases in levels of factor VIII and increases in D-dimer than do patients with liver failure.

A combination of conventional coagulation tests usually does not provide an accurate overall assessment of in vivo hemostasis in patients with advanced liver disease at any given time. Global coagulation tests, such as thrombelastography (ROTEM), thrombin generation assay, and clot waveform analysis (Chapter 157), would seem to lend themselves ideally to assessing bleeding or thrombotic risk and monitoring the overall hemostatic state of a complex coagulopathy like the one encountered in patients with liver disease. While ROTEM is increasingly used perioperatively in liver transplantation, the clinical utility of these global coagulation assays in chronic liver disease has not yet been well validated. In a randomized study of patients with advanced cirrhosis with active coagulopathy and bleeding, a thromboelastography-guided transfusion strategy led to a significantly lower use of blood components compared with standard of care, without failure to control bleeding, failure to prevent rebleeding, or mortality.[A2]

TREATMENT

Simple clinical coagulation tests such as the PT/INR are of little value in predicting bleeding problems in patients with liver disease,[13] and there is a dearth of evidence that blood component transfusions can predictably avert bleeding complications based on certain cut-off values of PT/INR or platelet count. These observations have driven a significant movement toward more restrictive transfusion strategies in patients with liver disease. Restrictive transfusion policies are now widely used in liver transplantation and have led to significant reductions in intraoperative blood loss and red cell transfusion requirements. By reducing central venous pressures, and consequently portal pressures, performing intraoperative phlebotomy has decreased blood loss with liver transplantation.

Routine transfusion of FFP for prophylaxis of bleeding in coagulopathic liver disease patients is not recommended because patients are unlikely to benefit.[14] Response to FFP is unpredictable and usually does not fully normalize the PT/INR even when multiple units are transfused, in part because FFP and especially stored thawed plasma itself often does not have an INR of less than 1.3. Some institutional guidelines have recommended empirically giving an intravenous dose of vitamin K, which may slightly reduce the PT/INR in liver failure, as well as transfusing cryoprecipitate if the plasma fibrinogen is less than 100 mg/dL (as a concentrated source of fibrinogen) in patients with or without active bleeding who are undergoing invasive procedures. There is little experience with the efficacy of four-factor prothrombin complex concentrate (PCC, Kcentra), which is currently approved for urgent reversal of vitamin K antagonists. Therapeutic plasma transfusion (10 mL/kg) is usually reserved for patients who are actively bleeding despite other treatments, including platelet transfusions if indicated.

In addition to the uncertainty regarding platelet count thresholds for platelet transfusion in patients with liver disease, there are other considerations in those who have portal hypertension with congestive splenomegaly and hypersplenism. Normally, about one third of the total peripheral platelet pool is sequestered in the spleen at any given time. In a patient with hypersplenism, platelet sequestration in the spleen can expand to as much as 90%, depending on the size of the spleen. Much of this splenic platelet pool can be mobilized into the circulation with catecholamines. It is unknown whether this phenomenon also occurs in response to endogenous catecholamines, but it is plausible that the stress of a hemostatic challenge could induce a transient increase in platelet counts, making the baseline level of thrombocytopenia in these patients a significant underestimation of what actually occurs in vivo. Related to the potentially marked expansion of the splenic platelet pool with hypersplenism, transfusion of a given amount of platelets often does not produce the expected "bump" in platelet count, and more units of platelets might be needed to achieve a calculated recovery in peripheral blood. The use of a thrombopoietin-receptor agonist to increase the platelet count is contraindicated based on a randomized trial using eltrombopag to increase the platelet count of thrombocytopenic patients (platelets <50,000 per μL) with chronic liver disease, which was prematurely terminated because of an excess of cases of portal vein thrombosis in the treatment group.

Because of the increased risk of thrombosis, as well as bleeding, in patients with chronic liver disease, prophylactic anticoagulation, especially when hospitalized or immobilized, should not be withheld. Prophylactic doses of low-molecular-weight heparin are safe to use. If there is coexisting kidney disease that precludes its use, prophylactic doses of unfractionated heparin or warfarin can be substituted, although monitoring of the latter may be complicated by a preexisting prolonged INR. In patients who are actively bleeding or have a very low platelet count, mechanical thromboprophylaxis can be substituted for pharmacologic thromboprophylaxis.

VITAMIN K DEFICIENCY

Vitamin K is required for γ-carboxylation of glutamic acid residues of the procoagulant factors II (prothrombin), VII, IX, and X and the anticoagulant factors protein C and protein S via the enzyme, γ-glutamyl carboxylase (GGCX). This post-translational modification normally renders these proteins functionally active in coagulation. The PT is more sensitive than the aPTT in detecting vitamin K deficiency states because factor VII, the only vitamin K–dependent factor that is in the extrinsic pathway of coagulation, is the most labile of these proteins.

The two major sources of vitamin K are dietary intake and synthesis by the bacterial flora of the intestine. In the absence of malabsorption, nutritional deficiency alone rarely causes clinically significant vitamin K deficiency. However, when eradication of gut flora is combined with inadequate dietary intake, as commonly occurs when critically ill patients in intensive care units have no oral intake and are receiving broad-spectrum antibiotics for prolonged periods, clinically significant vitamin K deficiency can be observed. Vitamin K deficiency can also develop in patients receiving total parenteral nutrition unless the infusions are supplemented with vitamin K. Certain mutations of the gene encoding GGCX can also cause a bleeding diathesis.

Vitamin K is absorbed predominantly in the ileum and requires the presence of bile salts. Clinically significant vitamin K deficiency occurs with malabsorption of fat-soluble vitamins secondary to obstructive jaundice (Chapter 141) or with malabsorption caused by intrinsic small bowel diseases, including celiac sprue, short bowel syndrome, and inflammatory bowel disease (Chapters 126 and 127).

Warfarin acts as an anticoagulant by competitive antagonism of vitamin K. Rare cases of hereditary deficiency of the vitamin K–dependent coagulation factors may cause a lifelong bleeding tendency.

Correction of vitamin K deficiency, when it is clinically significant, can be achieved with oral supplementation, unless malabsorption is present, in which case parenteral vitamin K (10 mg subcutaneously daily) should be administered. Patients on vitamin K antagonist therapy who have a supratherapeutic INR between 4.5 and 10.0 without bleeding are not likely to benefit from vitamin K administration in addition to stopping the anticoagulant.[A3] Emergency treatment of bleeding caused by vitamin K deficiency is transfusion of fresh-frozen plasma or four-factor prothrombin complex concentrate.

162 TRANSFUSION MEDICINE

BETH H. SHAZ AND CHRISTOPHER D. HILLYER

Blood transfusion can be lifesaving and is currently the safest it has ever been. However, blood transfusion is associated with multiple adverse outcomes, including both noninfectious and infectious complications. The benefits and risks of transfusion can be considered for each patient using evidence-based, multidisciplinary approaches to reduce unnecessary transfusions and improve patients' outcomes. As a result, the number of units of blood transfused has declined substantially in the United States and worldwide. In the United States, for example, about 10.6 million units of red blood cells (RBCs) are now transfused annually, a decrease from the high of 14.8 million units in 2008.[1]

BLOOD COMPONENTS

The majority of blood collections are whole blood, which can then be separated into plasma, platelets, and red blood cell (RBC) components. In the United States, 85% of RBC units are manufactured from whole blood and more than 90% of platelet components are collected by apheresis.

The majority of blood is transfused as component therapy, tailored to the need of a specific patient. Blood components such as RBCs, plasma, platelets, or granulocytes are obtained either from donation of whole blood or via apheresis (Table 162-1). Each component is stored under their respective optimal conditions; RBCs are refrigerated with additive solutions to improve long-term storage, plasma is frozen to preserve clotting factors, and platelets are stored at room temperature to preserve function and post-transfusion survival. As needed, components can be modified (e.g., irradiated) or selected (e.g., hemoglobin S negative) to meet specific patient requirements.

WHOLE BLOOD

Whole blood contains RBCs, platelets, and plasma. It is stored refrigerated unless used shortly after collection. The shelf-life depends on the storage conditions and preservation solution used. Whole blood provides oxygen-carrying capacity (RBCs) and coagulation support (plasma and platelets). Whole blood has largely been replaced by individual blood components because most patients only require one component (RBCs, platelets, or plasma).

However, whole blood can be useful particularly for trauma patients. The military uses a walking donor program for fresh whole blood, which is stored at 22° C for less than 24 hours. This product has addressed blood component shortages, particularly for platelet products, in austere environments. For civilian trauma, some institutions use cold stored (2° to 6° C) whole blood, which may or may not be leukoreduced (i.e., depleted of leukocytes).

RED BLOOD CELL COMPONENTS

RBC components are usually prepared from whole blood by removing 200 to 250 mL of plasma after centrifugation. RBC components can also be manufactured by apheresis, which can collect two components from a single donor. RBC components are stored at 1° to 6° C, which allows for 42-day storage. General characteristics of RBC components include 130 to 240 mL of RBCs, 50 to 80 g of hemoglobin, and 150 to 250 mg of iron per unit. The total volume (250 to 350 mL), and hematocrit (55 to 80%), vary depending on the volume of blood collected (450 versus 500 mL) and the specific preservative and additive solution used, which also determine its shelf life. RBCs have a hematocrit of 65 to 80% and a shelf life of 21 days when stored in citrate-phosphate-dextrose (CPD), a hematocrit of 65 to 80% and a shelf life of 35 days when stored in CPDA-1, and a hematocrit of 55 to 65% and a shelf life of 42 days when stored in additive solutions. In the United States, most RBC components are stored in additive solutions and contain small amounts of plasma, platelets, and leukocytes, unless the latter have been removed by leukoreduction filtration (which also removes platelets). Canada and many countries in Europe have a universally leukoreduced blood supply.

RED BLOOD CELL COMPONENT MODIFICATION

RBCs and other blood components can be modified to mitigate the complications of transfusion, such as transmission of infectious agents, and to enhance the preservation of rare components. Modified blood components include leukoreduced, irradiated, pathogen reduced, frozen (also known as cryopreservation), and washed components.

TABLE 162-1 BLOOD PRODUCT CHARACTERISTICS

PRODUCT	VOLUME	COMPOSITION	STORAGE CONDITIONS	STORAGE LENGTH	COMMENTS
Red blood cells	300-350 mL	200 mL RBCs, 30-40 mL plasma, 100-110 mL anticoagulant and additive solution	1-6° C	CPD: 21 days CPDA-1: 35 days AS: 42 days	• Leukoreduced: $<5 \times 10^6$ leukocytes • Red blood cells must be ABO compatible with patient plasma • D compatible for females with childbearing potential
Platelets	50 mL per whole blood derived platelet component; 200-400 mL/apheresis component	Platelets suspended in sufficient plasma or platelet additive solution	20-24° C with constant gentle agitation	5 days or 7 days with additional bacterial mitigation Pooled in an open system: 4 hrs	• Whole blood derived platelets: 5.5×10^{10} platelets/unit • Whole blood derived platelets into pools of 4-6 units • Apheresis platelets: 3×10^{11} platelets • Pool or apheresis, leukoreduced: $<5 \times 10^6$ leukocytes • ABO or D compatible is not required
Plasma	200-250 mL	One mL of plasma contains one unit of coagulation factor activity	−18° C; 1-6° C after thawing	Frozen shelf life: 1 yr FFP/FP24/PF24RT24 after thaw: 24 hrs Thawed plasma: 5 days	• FFP: Plasma frozen within 8 hrs of phlebotomy • FP24: Plasma frozen within 24 hrs of phlebotomy • PF24RT24: Plasma frozen within 24 hrs after phlebotomy held at room temperature up to 24 hrs after phlebotomy • Thawed plasma: FFP/FP24/FP24RT24 stored for up to 4 days beyond outdate • Plasma must be ABO compatible with patient RBCs • D compatible is not required
Cryoprecipitate	10-15 mL/unit	80-120 units Factor VIII, >150 mg Fibrinogen, Factor XIII, vWF	−18° C; room temperature after thawing	Frozen shelf life: 1 yr Thawed/pooled in an open system: 4 hrs Thawed/pooled in a closed system: 6 hrs	• ABO and RhD compatible cryoprecipitate is not required

AS = additive solution; CPD = citrate-phosphate-dextrose (anticoagulant); CPDA = citrate-phosphate-dextrose-adenine (anticoagulant); FFP = fresh frozen plasma; RBCs = red blood cells; vWf = von Willebrand factor.

ABSTRACT

Blood transfusion can be lifesaving and is currently the safest it has ever been. However, blood transfusion is associated with multiple adverse outcomes, including both noninfectious and infectious complications. Some mitigation strategies include donor testing and pathogen inactivation, irradiation, and leukoreduction of the products. The benefits and risks of transfusion must be considered for each patient for optimal outcome. Multidisciplinary blood management programs can reduce unnecessary transfusions and improve patients' outcomes. The management of massive bleeding continues to evolve with the use of whole blood, higher ratios of plasma and platelets to red blood cell units, thromboelastography testing, and use of tranexamic acid. Antigen-matched red blood cells can decrease the risk of alloimmunization in patients who require frequent transfusions.

Leukoreduction

To remove 99.9% of the white blood cells (yielding $<5 \times 10^6$ white blood cells per component), most RBC and platelet components transfused in the United States are leukoreduced. This process decreases the risk of febrile nonhemolytic transfusion reactions, transfusion-transmitted cytomegalovirus (CMV) and other leukocyte-transmitted infections, HLA alloimmunization, and a transient depression of the immune system after transfusion.

Irradiation and Cryopreservation

Irradiation of cellular blood components prevents transfusion-associated graft-versus-host disease (GVHD). Irradiation of RBCs shortens their storage period.

Freezing of RBCs extends their storage capability to 10 or more years. RBCs with rare phenotypes can therefore be frozen and banked for prolonged periods and be more readily available for patients who have antibodies to high-frequency antigens or rare combinations of antigens. After thawing, frozen RBCs must be washed to remove the cryoprotectant (glycerol). Because washed cellular blood components are depleted of plasma proteins, they are the preferred products for patients with a history of allergic, anaphylactoid, or anaphylactic reactions. Washed RBCs expire 24 hours after washing.

Pathogen Reduction

Pathogen reduction inactivates nucleic acids in viruses and bacteria and thus reduces the risk of transfusion-transmitted pathogens, both known and unknown. It also inactivates residual white blood cells, thereby eliminating the need for irradiation. Pathogen-reduced platelets[2] and plasma are used preferentially in some European countries and are increasingly being used in the United States. Pathogen-reduced plasma, particularly plasma treated with a solvent detergent, has a very low adverse event rate. RBC components derived from pathogen-reduced whole blood are approved in Europe, the Middle East, and Africa and are undergoing clinical trials for approval in other countries. Pathogen-reduced RBCs have a shortened shelf-life. In the United States, pathogen-reduced cryoprecipitate is approved for use in acquired fibrinogen deficiency or for replacement of factor XIII or von Willebrand factor when specific factor concentrates are not available.

PLATELET COMPONENTS

Platelet components can be produced from whole blood or apheresis collections and generally have a volume of approximately 300 mL. Platelets derived from whole blood are commonly referred to as *random donor platelets*, *platelet concentrates*, or *buffy coat platelets*. Each unit derived from whole blood contains approximately 0.5×10^{11} platelets. Typically 5 units are pooled to provide a therapeutic dose of 3.0×10^{11} platelets. Platelets collected by apheresis (or plateletpheresis) are referred to as *single donor platelets* or *apheresis platelets*. The required minimum content for a platelet component collected by apheresis is 3.0×10^{11} platelets, but many apheresis-derived platelet collections contain two or three times the required minimum and are therefore split to make multiple platelet components from a single collection. Outside the United States, platelets are made from whole blood using the buffy coat method. These are then pooled and stored in either platelet additive solution or a single donor's plasma. Platelet components can be stored for up to 7 days.

Platelet components are screened for the presence of bacteria to prevent septic transfusion reactions. Also, platelet and plasma components are prepared to reduce the risk of transfusion-related acute lung injury by selecting male or never-pregnant female donors or testing previously pregnant donors for HLA antibodies. Finally, platelets stored in platelet additive solutions have less plasma and thus are less likely to result in allergic reactions and hemolytic reactions due to ABO incompatibility between the donor and recipient.

Another product modification, cold-stored platelets, is emerging for use in trauma or during major bleeding. In the United States, cold-stored (1° to 6° C) platelets are approved with a 14-day shelf life when standard room temperature platelets are not available. These platelets remain in circulation less than 24 hours compared to 5 to 7 days for platelets stored at room temperature.

PLASMA COMPONENTS

Plasma components can be produced from whole blood after centrifugation and removal of RBCs or by apheresis. Notably, the following information applies to the United States, but other countries have simpler terms for their plasma components. *Fresh frozen plasma* (FFP) is frozen at −18° C or colder within 8 hours of collection. Plasma frozen at −18° C or colder within 24 hours of collection is referred to as *plasma frozen within 24 hours after phlebotomy. Plasma frozen within 24 hours after phlebotomy held at room temperature up to 24 hours after phlebotomy* prepared from apheresis collections is also available. Once frozen, plasma has a frozen shelf life of 1 year. Prior to transfusion, plasma must be thawed to 30° to 37° C, a process that takes 20 to 30 minutes. Thawed plasma should be transfused immediately or stored at 1° to 6° C for up to 24 hours. Thawed plasma can be stored for up to 4 additional days at 1° to 6° C to prevent wastage. FFP contains approximately 1 IU/mL of each clotting factor. From a clinical perspective, all plasma products are essentially equivalent.

Other plasma components which are less commonly used include *cryoprecipitate-reduced plasma* and *liquid plasma*. Cryoprecipitate-reduced plasma, which is the plasma remaining after cryoprecipitate is removed, is mostly deficient in factor VIII, fibrinogen, von Willebrand factor, factor XIII, and fibronectin. The sole clinical indication for cryoprecipitate-reduced plasma is in the treatment of thrombocytopenic thrombotic purpura (Chapter 158). Liquid plasma, stored at 1° to 6° C, is separated from whole blood and transfused no later than 5 days after the expiration date of the whole blood. This product contains viable lymphocytes, so it requires irradiation to prevent transfusion-associated graft-versus-host disease in high-risk recipients, such as patients who are immunocompromised.

CRYOPRECIPITATE

Cryoprecipitate is manufactured by thawing FFP at 1° to 6° C. During this thawing process, a precipitate forms (the cryoprecipitate), is separated, and is refrozen. Cryoprecipitate is selectively enriched in fibrinogen, fibronectin, factor VIII, von Willebrand factor, and factor XIII. Cryoprecipitate and its supernatant (cryoprecipitate-poor plasma) are separately refrozen and stored for up to 1 year after collection.

Each unit of cryoprecipitate contains at least 150 mg fibrinogen and 80 IU of factor VIII. A single 10 to 15 mL unit of cryoprecipitate should increase the fibrinogen concentration by approximately 50 mg/dL per 10 kg of body weight. Most blood centers provide prepooled cryoprecipitate, which typically consists of 5 units of cryoprecipitate and which is easier for the hospital transfusion service to prepare. For adult patients, the typical order is a dose of 5 to 10 units of cryoprecipitate.

GRANULOCYTES

Granulocytes have a 24-hour shelf life and are stored at room temperature without agitation. Mostly they are collected by apheresis using hydroxyethyl starch to improve collection. In order to increase the number of granulocytes collected, the donor may be stimulated with steroids to yield components with approximately 1×10^{10} granulocytes and donors stimulated with steroids and granulocyte colony-stimulating factor (G-CSF; Chapter 142) to yield components with approximately 1×10^{11} granulocytes. Apheresis granulocytes have approximately 200 mL volume, 10 to 50 mL of RBCs, 3×10^{11} platelets (equivalent to a platelet component), and plasma. All granulocytes should be irradiated, cannot be leukoreduced, and should be transfused as soon as possible.

PRETRANSFUSION TESTING

Routine pretransfusion testing of blood components includes receipt of an appropriately labeled patient specimen by the transfusion service, testing of the patient's specimen for ABO group and D type and for the presence of unexpected antibodies, and crossmatching of RBC components with the patient's sample.

In emergency situations and before crossmatch compatible blood components are available, group O RBCs and group AB plasma (some institutions use group A plasma) may be appropriately transfused.

Critical to safe blood transfusion is a properly labeled pretransfusion blood specimen from the intended transfusion recipient. Most hemolytic transfusion reactions are caused by misidentification or labeling errors in pretransfusion blood specimens. Radio-frequency identification technology improves the safety and efficiency.

A "type and screen" involves typing the patient's RBCs for ABO and Rh (also known as RhD or D) type, as well as screening the patient's plasma for clinically significant RBC antibodies. A "type and crossmatch" also includes the selection, crossmatching, and reserving of appropriate RBC components for the transfusion recipient. Many institutions have a maximum surgical blood order schedule, which indicates when a type and screen is ordered and how many components should be reserved for each type of surgical procedure.

RBC antibodies of clinical significance are formed in response to pregnancy or transfusion; they may cause hemolysis or shortened survival of transfused RBCs carrying the reciprocal antigen (i.e., acute or delayed hemolytic transfusion reaction). For this reason, the intended recipient's plasma is screened for

the presence of these unexpected antibodies prior to RBC transfusion. If a patient has a clinically significant antibody, the transfusion service will select and reserve the appropriate RBC components that do not carry the reciprocal antigen. The process of identifying a patient's RBC antibody and crossmatching the appropriate RBC components can take hours or even days, depending on the antibody or antibodies found. It can be particularly problematic when the intended recipient has autoantibodies (Chapter 146).

How far in advance a specimen can be drawn is determined by institutional policies. In patients with a negative antibody screen and no history of transfusion or pregnancy in the preceding 3 months, specimens may be drawn up to 1 month before surgery. However, if the patient has been transfused or has been pregnant in the preceding 3 months, a pretransfusion specimen is valid only for 3 days. Most hospitalized patients require a new specimen every 3 days.

ABO/D COMPATIBILITY

Individuals naturally have antibodies against the ABO groups they do not carry (i.e., group O individuals have anti-A and anti-B, group A individuals have anti-B, group B individuals have anti-A, and group AB individuals have none). RBC components must be major ABO compatible and usually D compatible. Group O is the universal RBC component because the RBCs carry no A or B group antigens, whereas group AB RBCs can only be transfused to group AB individuals, group A RBCs can only be transfused to group A or AB individuals, and group B RBCs can only be transfused to group B or AB individuals. Incompatible RBC transfusions may result in acute hemolytic transfusion reactions.

In contrast, D-negative individuals do not make anti-D unless exposed to D-positive RBCs through previous pregnancy or transfusion. D-negative females of childbearing potential must receive D-negative RBCs, unless unavailable in emergency situations, to prevent anti-D formation which may result in hemolytic disease of the fetus and newborn. If there is a shortage of D-negative RBCs, males and females not of childbearing potential (usually defined as age ≥50 years old) can receive D-positive components. The risk of anti-D formation from D-positive RBC unit is about 10 to 20%.

Plasma, which contains antibodies, should be minor ABO compatible such that group AB plasma is the universal product. Group A plasma can be transfused to group A or O individuals, group B to group B or group O individuals, and group O to group O individuals. Group A plasma is being used in massive transfusion settings due to the limited availability of group AB plasma (4% of the population is group AB). This practice appears safe, particularly given that these patients are receiving group O RBCs and are switched to type-specific components once the blood type is known. Plasma is not D-matched because no RBCs are in the product.

Platelets are typically transfused with ABO matching. ABO compatibility results in higher post-transfusion platelet count increment. To decrease the risk of hemolytic transfusion reactions from incompatible plasma, low titer (of anti-A) group O products are used. Risk of anti-D with D-positive to D-negative patients is less than 1%. Granulocytes should be major ABO compatible due to their contamination with RBC and subsequent risk of acute hemolytic transfusion reaction.

BLOOD SAFETY

Adverse events of blood transfusion occur in 0.2% of transfusions, and about 7% of these events are serious. Adverse events can be classified as acute (within hours) or delayed (days to years), and as noninfectious or infectious (Table 162-2 and Table 162-3).[3] Infectious risks include emerging infections, such as *Babesia*, and traditional infections, such as hepatitis B or C. With improvement in donor screening for transmissible diseases, more focus has been on reducing noninfectious transfusion reactions.[4,5]

TABLE 162-2 NONINFECTIOUS TRANSFUSION-ASSOCIATED EVENTS

TRANSFUSION-ASSOCIATED ADVERSE EVENT	RISK PER UNIT TRANSFUSED IN THE UNITED STATES
Acute hemolytic transfusion reaction	≈1 : 110,000 transfusions
Febrile nonhemolytic transfusion reaction	≈1 : 1100
Allergic transfusion reaction	≈1 : 1200 ≈1 : 15,500 severe
Transfusion-associated circulatory overload	≈1 : 9000
Transfusion-related acute lung injury	≈1 : 140,000
Hypotensive transfusion reactions	≈1 : 32,000
Transfusion-associated dyspnea	≈1 : 28,000
Delayed hemolytic transfusion reaction	≈1 : 32,000
Delayed serologic transfusion reaction	≈1 : 8000
Transfusion-associated graft-versus-host disease	<1 : 10,000,000
Post-transfusion purpura	≈1 : 10,000,000

TABLE 162-3 INFECTIOUS DISEASE WINDOW PERIOD AND RESIDUAL RISK

TEST	WINDOW PERIOD (DAYS)	RESIDUAL RISK OF TRANSFUSION
HIV MP-NAT	9	≈1 : 1,800,000
HIV EIA	21	
HCV MP-NAT	7	≈1 : 1,600,000
HCV EIA	51-58	
HBsAg	30-38	≈1 : 300,000
HBV NAT	40-50 (MP) and 15-34 (ID)	≈1 : 1,500,000
HTLV	80	≈1 : 3,300,000
Syphilis		1 reported case in the United States in the last 50 years
Chagas disease		7 reported cases in the U.S.; none since testing
WNV NAT		Last case in 2012
Bacterial contamination		1 : 200,000-1,000,000 with addition of multiple mitigation strategies

EIA = enzyme immunoassay; HBsAg = hepatitis B virus surface antigen; HBV NAT = hepatitis B virus nucleic acid test; HCV = hepatitis C virus; HIV = human immunodeficiency virus; HTLV = human T-cell leukemia-lymphoma virus; ID = individual donor nucleic acid testing; MP-NAT = mini-pool nucleic acid testing; WNV NAT = West Nile virus nucleic acid test.

NONINFECTIOUS ADVERSE EFFECTS OF BLOOD TRANSFUSION

ACUTE HEMOLYTIC TRANSFUSION REACTION

Acute hemolytic transfusion reactions occur when preformed recipient antibodies bind to transfused RBC antigens, thereby resulting in the formation of an antigen-antibody complex.[6] This complex activates the complement cascade and causes intravascular hemolysis. Most commonly, acute hemolytic transfusion reactions are severe reactions due to ABO incompatibility, usually because transfused RBC antigens are incompatible with the recipient's plasma (e.g., group A RBCs into group O recipient), and less commonly when transfused plasma contains antibodies against the recipient's RBC antigens (e.g., group O plasma into group A recipient). Acute hemolytic transfusion reactions can also be associated with antigen-antibody complexes outside of the ABO system. The destruction of RBCs also may result in mechanical hemolysis unrelated to the transfusion.

The incidence of acute hemolytic transfusion reactions is approximately 1 : 110,000 transfusions, and these rates have substantially decreased over time. About 70% of transfusion reactions are due to RBCs and 30% due to platelet transfusions. ABO-incompatible RBC transfusions most commonly occur with mistransfusion, when the patient receives an incorrect unit. Mistransfusion is usually caused by human error, including improper identification of the intended recipient during pretransfusion sample collection, improper ABO typing of the blood component or the intended recipient, or improper identification of the recipient or the blood component at the time of transfusion.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The signs and symptoms of acute hemolytic transfusion reactions are fever, chills/rigors, anxiety, chest and abdominal pain, flank and back pain, nausea, vomiting, dyspnea, hemoglobinuria, diffuse bleeding, and oliguria/anuria. If

an acute hemolytic transfusion reaction is suspected, the transfusion should be stopped immediately, the reaction should be reported to the transfusion service for investigation, and the unit should be returned to the blood bank. Diagnosis is based on laboratory evidence of hemolysis (e.g., decreased hemoglobin, decreased haptoglobin, hemoglobinuria, and elevated lactate dehydrogenase) and evidence of incompatible blood transfusion (e.g., positive direct antiglobulin test and incompatible crossmatch). Approximately 50% of ABO-incompatible RBC transfusions have no adverse effect, but 5% are fatal.

TREATMENT AND PREVENTION

Treatment includes saline infusion (and potentially the addition of low-dose dopamine) to maintain blood pressure and adequate urine output; a diuretic (e.g., furosemide) to increase renal blood flow; and plasma, cryoprecipitate, platelets, and heparin as needed for disseminated intravascular coagulopathy (Chapter 161).

Acute hemolytic transfusion reactions can be mitigated by decreasing the risk of ABO incompatible blood transfusion. Mislabeling of patient samples remains the major factor contributing to ABO incompatibility. Processes to address this problem include improved tracking and labeling of specimens, use of radiofrequency identification systems, and policies to require two separate blood draws for ABO typing prior to releasing type-specific RBC components.

Febrile Nonhemolytic Transfusion Reaction

Febrile nonhemolytic transfusion reaction, with an incidence of approximately 1 : 1100 transfusions, is defined as a temperature increase of 1° C or more or greater than 38° C and/or chills/rigors occurring within 4 hours of cessation of transfusion.[7] The incidence of febrile nonhemolytic transfusion reactions has significantly decreased with the widespread use of leukoreduction.

By definition, the temperature increase cannot be attributed to other etiologies. In platelet components, febrile nonhemolytic transfusion reactions are caused by leukocyte-derived cytokines that accumulate in the component during storage. With RBC components, these reactions are caused by donor leukocytes interacting with patient white blood cell antibodies.

If a febrile nonhemolytic transfusion reaction is suspected, the transfusion should be stopped and reported to the transfusion service to exclude a more serious transfusion-associated adverse event. Supportive care should be administered.

Allergic Transfusion Reaction

Allergic transfusion reactions have an overall incidence of approximately 1 : 1200 transfusions. Most allergic reactions are mild, but about 8% are severe. Platelet transfusions are the blood component most often associated with allergic reactions. Platelets stored in platelet additive solution have less plasma and thus a decreased allergic reaction rate of 0.3% compared with 0.8% for platelets stored in plasma. Solvent/detergent-treated plasma from pooled donors also has lower allergic reaction rates. Anaphylactic reactions (Chapter 233) may be secondary to anti-IgA, which can occur in patients with IgA deficiency.

Mild reactions consist of urticaria with or without generalized pruritus or flushing. More severe symptoms include hoarseness, stridor, wheezing, dyspnea, hypotension, gastrointestinal symptoms, and shock. Patients who have severe allergic reactions should be tested for IgA deficiency and the presence of anti-IgA.

TREATMENT AND PREVENTION

Mild reactions can be treated by temporarily stopping the transfusion and administering antihistamines, whereas severe reactions require discontinuation of the transfusion and treating with epinephrine, H1-receptor antagonists, and corticosteroids. (Chapter 233). Premedication with antihistamines decreases the incidence of allergic reactions, but is recommended only in patients who have a history of allergic reactions. If anti-IgA is identified, the patient should receive plasma components from IgA deficient donors or washed RBC and platelets components.

Transfusion-Associated Circulatory Overload

Transfusion-associated circulatory overload, with an incidence of approximately 1 : 9000 transfusions, results from circulatory overload following transfusion. Risk factors are age older than 70 years, a post-transfusion B-type natriuretic peptide (BNP) greater than 1000 pg/mL, a positive fluid balance of greater than 3 L, and more units transfused within 6 hours. Symptoms and signs include dyspnea, tachypnoea, decreased oxygen saturation, orthopnea, cough, chest tightness, cyanosis, hypertension, and headache. These signs and symptoms usually present at the end of transfusion but may occur up to 12 hours post-transfusion. Diagnosis is based on the presence of fluid overload and elevated levels of BNP or NT-pro BNP (Chapter 45). Management includes discontinuing the transfusion, diuretic therapy, oxygen supplementation, and sitting the patient upright (Chapter 46).

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI), with an incidence of approximately 1 : 140,000 transfusions, is noncardiogenic pulmonary edema that is associated with the transfusion and that occurs within 6 hours of cessation of transfusion.[8] The incidence of transfusion-related acute lung injury has substantially decreased[9] with the implementation of male-only, HLA antibody–negative, or nulliparous female plasma and platelet donors. Additionally, solvent/detergent-treated plasma has rarely been associated with cases of transfusion-related acute lung injury.

Transfusion-related acute lung injury is most commonly seen following platelet transfusions, and the majority of events are serious. Patient-related risk factors include higher IL-8 levels, liver surgery, chronic alcohol use disorder, shock, higher peak airway pressure while being mechanically ventilated, current smoking, positive fluid balance. Transfusion-related risk factors include the receipt of plasma from female donors and a higher volume of HLA class II human neutrophil antigen positive antibodies. Signs include hypoxemia with radiographic evidence of bilateral infiltrates. Transfusion-related acute lung injury is caused by neutrophil and pulmonary endothelial activation, usually a result of transfused donor white blood cell antibodies, including human leukocyte antigen (HLA) antibodies and human leukocyte antigen antibodies. These donor antibodies react with the recipient's white blood cells in the pulmonary vasculature, thereby causing leukoagglutination, activation of the complement cascade, cytokine release, and pulmonary edema. More rarely, transfusion-related acute lung injury is caused by the converse mechanism in which recipient white blood cell antibodies react against transfused donor white blood cells.

When hypoxemia occurs within 6 hours of transfusion in the absence of other risk factors for acute lung injury, the transfusion-related acute lung injury is called type 1, whereas it is called type 2 in patients who have such risk factors or already have at least mild preexisting acute respiratory distress syndrome or risk factors for it (e.g., pneumonia, inhalation injury, trauma, sepsis, drowning, pancreatitis, burn, shock, cardiopulmonary bypass, or drug overdose).

TREATMENT AND PROGNOSIS

In cases of suspected transfusion-related acute lung injury, the transfusion should be discontinued. Medical management is primarily supportive, commonly with supplemental oxygen and endotracheal intubation if needed. Diuresis is not indicated, and the role of corticosteroids is unclear. The majority of patients improve within 2 to 4 days, although transfusion-related acute lung injury has a 5 to 10% mortality rate.

Hypotensive Transfusion Reactions

Hypotensive transfusion reactions, with an incidence of approximately 1 : 32,000, are usually associated with transfusions of RBCs or platelets. These reactions appear to be related to the generation of bradykinin, thereby resulting in vasodilation and hypotension. Hypotensive reactions have most commonly been reported in association with the use of negatively charged bedside leukoreduction filters in patients being treated with angiotensin-converting enzyme inhibitors. The use of prestorage leukoreduction in lieu of bedside leukoreduction limits the incidence of these reactions. Hypotensive transfusion reactions typically resolve with cessation of transfusion.

Transfusion-Associated Dyspnea

Transfusion-associated dyspnea, with an incidence of approximately 1 : 28,000 transfusions, results in acute respiratory distress within 24 hours of transfusion cessation. It is a diagnosis of exclusion, when allergic reactions, transfusion-associated circulatory overload, and transfusion-related acute lung injury have been excluded.

Delayed Hemolytic and Serologic Transfusion Reaction

Delayed hemolytic transfusion reactions, with an incidence of approximately 1 : 32,000 transfusions, occur when RBC transfusion causes an alloantibody

response, thereby resulting in decreased RBC survival. If an alloantibody response is noted in the absence of RBC destruction, it is termed a delayed *serologic* transfusion reaction, which has an incidence of approximately 1 : 8000 transfusions. If alloantibodies are formed within days of transfusion, it is presumed to be an anamnestic alloantibody response in an individual who had previously formed antibodies, usually from an earlier transfusion or pregnancy. If alloantibodies are formed within weeks of transfusion, it is presumed to be a primary alloantibody response.

Delayed hemolytic transfusion reactions are characterized by an unexpected decrease or less than expected increase in the recipient's hemoglobin post-transfusion. Other signs and symptoms, which are typically much less severe than those associated with acute hemolytic transfusion reactions, include fever, chills, jaundice, malaise, back pain, and rarely renal failure. To prevent future reactions, the patient should receive antigen-negative RBCs for future transfusions. The primary mitigation strategy is prophylactic RBC antigen matching.

A severe form of delayed hemolytic transfusion reaction is hyperhemolytic transfusion reaction. This rare reaction, which is most often reported in patients who have sickle cell disease (Chapter 149) or thalassemia (Chapter 148), results in destruction of both donor and recipient RBCs, thereby leading to more severe anemia. Additionally, the patients usually have reticulocytopenia. RBC alloantibodies or autoantibodies may or may not be present. The pathophysiology remains unclear. Treatment includes erythropoietin, intravenous immunoglobulin, corticosteroids, rituximab, tocilizumab, and eculizumab under expert supervision. Future RBC transfusions should be administered cautiously.

Transfusion-Associated Graft-versus-Host Disease

Transfusion-associated graft-versus-host disease (GVHD), with an incidence of less than 1 : 10,000,000 transfusions, results from the engraftment of transfused viable donor lymphocytes in an immunosuppressed recipient. The donor lymphocytes subsequently mount an immune response against the recipient, thereby resulting in pancytopenia, an erythematous rash or even generalized erythroderma, liver dysfunction, and gastrointestinal symptoms. Unlike GVHD associated with hematopoietic progenitor cell transplantation (Chapter 163), transfusion associated-GVHD has a nearly 100% fatality rate due to the profound pancytopenia.

Patients at increased risk for transfusion associated-GVHD include individuals with congenital immunodeficiencies, Hodgkin disease, acute leukemia, or other hematologic malignancies, as well as patients undergoing hematopoietic progenitor cell transplantation. Patients who receive HLA-matched blood components or blood components from close relatives, granulocyte transfusions, intrauterine transfusions, or neonatal red cell exchange are also at increased risk. At-risk patients should receive irradiated or pathogen-reduced cellular blood components, which prevent leukocytes from engrafting.

Post-Transfusion Purpura

Post-transfusion purpura, with an incidence of approximately 1 : 10,000,000 transfusions, is an immune thrombocytopenia caused by antiplatelet alloantibodies, most often anti-HPA-1a (Chapter 158). All types of blood components have been implicated, with transfusion triggering an antibody response to platelet antigens.

Post-transfusion purpura is characterized by acute, profound thrombocytopenia (platelet count <10,000/μL), unexplained purpuric rash, bruising, or mucosal bleeding 1 to 3 weeks post-transfusion. Thirty percent of affected patients have major hemorrhage, and 10% of patients have fatal hemorrhage. Diagnosis is based on the clinical presentation and the identification of platelet-specific alloantibodies. The primary treatment for post-transfusion purpura is intravenous immunoglobulin under expert supervision.

INFECTIOUS COMPLICATIONS OF TRANSFUSION

Criteria for transfusion-transmission of pathogens include: an asymptomatic infectious phase in the donor; an agent's viability during storage; a seronegative recipient population; and an agent capable of causing disease post-transfusion. The transfusion-transmitted infection rate is about 1 : 225,000, and this rate has substantially decreased over time worldwide. Higher rates occur with platelet transfusions, and the majority are severe reactions. About 50% of the reactions are bacterial and about 50% are parasitic, with rare viral transmission.

Blood safety relies upon several measures, including careful donor screening by questionnaire, the use of good manufacturing practices, and donor and component screening for infectious diseases. Currently, in the United States, blood donors are screened for infection with hepatitis B virus, hepatitis C virus, HIV-1 and HIV-2, human T-cell lymphotropic viruses (HTLV) types I and II, West Nile virus (WNV), syphilis, and *Trypanosoma cruzi*. Additionally, donors may be screened for cytomegalovirus and *Babesia* in high epidemic areas of the United States. Platelet components are also screened for bacterial contamination unless they have been pathogen-reduced.

Bacterial Contamination

The risk of a septic reaction is approximately 1 : 200,000 to 1,000,000 transfusions, with the risk decreasing as additional platelet bacterial contamination mitigation strategies are implemented.[10] Platelet components are primarily associated with bacterial contamination due to their storage at room temperature. The implementation of multiple steps for platelet units, including skin cleansing, diversion pouch, and bacterial screening, has resulted in approximately two-thirds decrease in septic reactions. Pathogen reduction decreases bacteria loads by more than four logs for most organisms, although several septic reactions have been reported from pathogen-reduced platelet transfusion in the United States[11] Additional mitigation strategies implemented in the United States and other countries reduce septic reactions to less than 1 : 500,000 transfusions include delayed or repeat bacterial culture and use of point-of-issue bacterial screening.[12]

Septic reactions should be suspected if the transfused patient has fever (≥38° C with rise ≥1° C) with rigors, hypotension, shock, tachycardia, dyspnea, or nausea/vomiting. The transfusion should be promptly stopped, supportive care should be instituted, and blood samples should be drawn for culture (aerobic and anaerobic times two) prior to initiating antibiotics. Thrombocytopenic neutropenic patients are most at risk for septic reactions, mostly due to *Staphylococcal aureus*.

Virus

Hepatitis B (Chapter 134) virus has an estimated transfusion transmission risk of approximately 1 : 1,500,000 transfusions. In the United States, blood components are screened by testing for Hepatitis B surface antigen (HBsAg), anti-HBc, and HBV nucleic acid testing (NAT).

Hepatitis C has an estimated transfusion transmission risk of approximately 1 : 1,600,000 transfusions. In the United States, blood components are screened by testing for anti-HCV and HCV NAT.

Human immunodeficiency virus (HIV) has an estimated transfusion transmission risk of approximately 1 : 1,800,000 transfusions. HIV-2 is found mainly in West Africa. In the United States, blood components are screened by testing for anti-HIV-1/HIV-2 and HIV-1/HIV-2 NAT.

Human T-cell lymphotropic virus (Chapter 360) has an estimated transfusion transmission risk of approximately 1 : 3,300,000 transfusions. In the United States, blood components are screened for HTLV-I and HTLV-II by testing for anti-HTLV-I/II.

Donor screening has substantially reduced the number of transfusion-transmitted cases of West Nile virus (Chapter 352), with the most recent U.S. case being reported in 2012. In the United States, blood components are screened by West Nile virus NAT. To improve testing logistics and cost, testing is initially performed on pooled samples, and then this process continues until increased regional disease activity is detected, at which time testing is on individual samples.

Four suspected cases of transfusion-transmitted Zika virus (Chapter 352) have been reported, all in Brazil, and none were associated with clinical sequelae in the recipients. Zika NAT testing was performed in the United States from 2016 to 2021, but then the FDA determined that Zika virus is no longer a relevant transfusion-transmitted infection. Now, neither testing nor pathogen reduction is required.

Other Infections

In the United States, blood components are screened for syphilis (Chapter 295) by nontreponemal or treponemal tests. No transfusion-transmitted syphilis infections have been reported in the last several decades due to the spirochete's poor viability during storage.

In the United States blood components are screened for *T. cruzi*, which is the causative agent of Chagas disease (Chapter 318), by testing for anti–*T. cruzi* antibody. In the United States, donors are tested only at their first donation. Since the advent of screening, no transfusion-related cases have been reported.

Screening of blood donors for *Babesia* (Chapter 324) is performed using either NAT or pathogen reduction in high epidemic states to prevent transfusion-transmitted babesiosis. The implementation of screening has decreased the incidence of transfusion-transmitted *Babesia,* which is dependent on the donor's residence and travel.

Many other pathogens have been reported to be transfusion transmitted, including *Anaplasma phagocytophilum* (Chapter 324), parvovirus B19 (Chapter 342), hepatitis A (Chapter 134), Dengue virus (Chapter 352), variant Creutzfeldt-Jakob disease (Chapter 371), and malaria (Chapter 316). Donors are screened by donor history questionnaire for malaria in the United States. Plasma for further manufacturing is tested for parvovirus B19 and hepatitis A.

INDICATIONS FOR BLOOD TRANSFUSION (TABLE 162-4)

RED BLOOD CELL TRANSFUSIONS

RBC transfusions are used to treat anemia when patients require increased oxygen carrying capacity, based on their individual clinical status and coexisting medical conditions. In an average adult, one RBC component (unit) should increase the hemoglobin by about 1 g/dL and the hematocrit by about 3%.

Almost 50 randomized controlled trials[A1,A2,13] have compared restrictive (hemoglobin between 7.0 g/dL and 8.0 g/dL) versus liberal (hemoglobin between 9.0 g/dL and 10.0 g/dL) transfusion thresholds in a variety of clinical contexts, including medical and surgical adult patients. Transfusing at lower versus higher hemoglobin levels results in equivalent rates of mortality, myocardial infarction, stroke, pneumonia, thrombosis, and infection. Clinical situations in which a higher transfusion threshold (e.g., >8.0g/dL) should be considered are patients who have symptomatic anemia, an acute coronary syndrome, an acute myocardial infarction,[A3] severe thrombocytopenia, or who require chronic transfusions. The COVID-19 pandemic resulted in sustained blood shortages worldwide, particularly for RBC products, thereby resulting in the adoption of blood conservation strategies, including splitting products and altering transfusion practices.[14]

PLATELET TRANSFUSIONS

Platelet transfusions are given to prevent or treat bleeding in thrombocytopenic patients (Chapter 158). Platelet transfusion may also be considered in patients with qualitative defects in platelet function. The threshold to transfuse platelets is determined by the patient's platelet count combined with underlying disease and the presence of clinical bleeding.

To prevent bleeding in patients with low platelet counts, patients can be transfused platelets prophylactically.[15] Platelets are indicated in patients with therapy-induced hypoproliferative thrombocytopenia at a platelet count of 10,000/μL or less. Platelet transfusions are also indicated in patients who are having an elective central venous catheter placement with a platelet count of less than 20,000/μL, patients having elective diagnostic lumbar puncture or non-neuraxial surgery with a platelet count of less than 50,000/μL, and in patients having major elective neurosurgery with a platelet count of less than 100,000/μL.

TABLE 162-4 EVIDENCE-BASED TRANSFUSION TRIGGERS

BLOOD COMPONENT	COMMONLY ACCEPTED INDICATIONS	TYPICAL INCREASE
RBC	Hb <7.0 g/dL Hb< 8.0 g/dL acute coronary syndrome/myocardial infarction	Hb: 1 g/dL or Hct: 3% after one unit of RBC
Platelets	<10,000/μL hospitalized adult patients with therapy-induced hypoproliferative thrombocytopenia <20,000/μL if febrile/septic, central venous catheter, or other minor procedures <50,000/μL if surgery, lumbar puncture, invasive procedure, or active bleeding <100,000/μL neurosurgery or central nervous system bleeding	30-60,000/μL after one platelet dose (a single apheresis component or 4-6 whole blood derived platelet concentrates [3×10^{11} platelets])
Plasma	Massive transfusion (plasma : RBC: 1 : 2) INR >2.0 prior to invasive procedure Replacement fluid for plasma exchange for thrombotic thrombocytopenic purpura	10-15 mL/kg increases factor levels by ≈20%
Cryoprecipitate	Fibrinogen <150 mg/dL with bleeding	≈7 mg/dL increase in fibrinogen per unit

Hb = hemoglobin; Hct = hematocrit; ICH = intracranial hemorrhage; INR = international normalized ratio; PCC = prothrombin complex concentrate; RBC = red blood cell.

Platelets also are administered therapeutically in patients who have low platelet counts, generally less than 50,000/μL, and if they are actively bleeding. Platelet transfusions are also indicated in patients who have undergone cardiac surgery with cardiopulmonary bypass, exhibit perioperative bleeding, and are either thrombocytopenic or have evidence of platelet dysfunction. In patients who have a massive hemorrhage, platelets should be administered at an appropriate ratio to RBC transfusions. Platelet transfusion is not recommended for patients who have an intracranial hemorrhage while receiving antiplatelet therapy.[A4]

In adults, a typical platelet dose is a single apheresis component or four to six whole blood-derived platelet concentrates pooled (3×10^{11} platelets). Lower dose platelet transfusions (e.g., $1.1 \times 10^{11}/m^2$ or $2.2 \times 10^{11}/m^2$) result in similar bleeding outcomes but require more platelet transfusions per patient.

The response to platelet transfusion can be assessed by a decrease in clinical bleeding and by measuring the post-transfusion increment in platelet count about 15 to 60 minutes after transfusion. A typical dose of platelets should increase the patient's platelet count by 30,000 to 60,000/μL.

A more formal evaluation of the platelet increment can be performed using the corrected count increment, which accounts for both the patient's size (via body surface area) and the number of platelets in the transfused component. The corrected count increment is calculated as:

$$\frac{\text{Body surface area}(m^2) \times \text{Platelet count increment} \times 10^{11}}{\text{Number of platelets transfused}}$$

A 1-hour corrected count increment greater than 7.5 is considered acceptable, whereas a corrected count increment value less than 7.5 is suggestive of platelet refractoriness.

Many clinical conditions can decrease the expected post-transfusion increment in the platelet count, including fever, sepsis, disseminated intravascular coagulation, splenomegaly with hypersplenism, active bleeding, and platelet or HLA alloantibodies or autoantibodies. ABO-compatible transfusions result in higher post-transfusion increment than ABO-incompatible transfusions. Patients who have multiple platelet transfusions may develop antibodies that blunt the response of the platelet count, and evaluation of platelet refractoriness usually includes screening for HLA compatibility and platelet antibodies. In this situation, HLA epitope-matched platelet transfusions provide a better response than standard HLA antigen-matched transfusions, with each epitope mismatch reducing the platelet count response by about 15%.[A5]

PLASMA TRANSFUSIONS

Plasma transfusions are generally used either to prevent or treat bleeding in patients with acquired coagulopathies. For the majority of patients with congenital coagulopathies, the specific and appropriate clotting factor concentrate should be administered (Chapter 160), such as von Willebrand factor, factor VIII, factor IX, fibrinogen, factor X, factor VIIa, factor XIII, prothrombin complex concentrate, and C1 inhibitor concentrate. These factors are either purified and virally inactivated human or recombinant proteins. If the specific factor is not available, plasma should be transfused.

Plasma should be administered to massively hemorrhaging patients at an appropriate ratio to red blood cell transfusions. Plasma can also be used to treat or prevent major bleeding in patients with multiple coagulation factor deficiencies, including disseminated intravascular coagulopathy (Chapter 161) and liver failure (Chapter 140).

Plasma is also indicated as replacement fluid for plasma exchange in patients with thrombotic thrombocytopenic purpura (Chapter 158) and other diseases.[16] Plasma may also be used as part of the replacement fluid for patients at risk of coagulation factor depletion, particularly patients who are on daily plasma exchange with albumin as replacement fluid.

The only clinical indication for plasma cryoprecipitate-reduced and thawed plasma cryoprecipitate reduced is thrombotic thrombocytopenic purpura (Chapter 158). The only indication for liquid plasma is for initial treatment of patients undergoing massive transfusion.

Plasma transfusion is not recommended for warfarin-related serious hemorrhage unless prothrombin complex concentrate is not available. Prothrombin complex concentrate, specifically 4-factor (factors II, VII, IX, and X), should be used instead of plasma for the rapid reversal of warfarin in patients who experience bleeding or require urgent surgery (Chapter 161). Plasma is not recommended for reversal of novel oral anticoagulants (e.g., direct thrombin inhibitors and direct factor Xa inhibitors).

The typical dose of plasma is 10 to 15 mL/kg. Because each plasma component is 200 to 300 mL, an average adult dose is 3 to 5 plasma components

(units). Coagulation factors are expected to increase by approximately 20% immediately after plasma infusion.

CRYOPRECIPITATE TRANSFUSIONS

Cryoprecipitate is used for fibrinogen replacement when levels fall below 100 mg/dL in acquired hypofibrinogenemia with disseminated intravascular coagulopathy (Chapter 161), liver failure (Chapter 140), the anhepatic phase of liver transplantation (Chapter 161), and massive transfusion with dilution coagulopathy. Cryoprecipitate may also be used for management of intracranial bleeding related to thrombolytic therapy (tissue plasminogen activator). Pathogen-reduced cryoprecipitated fibrinogen concentrate, which is derived from pathogen-reduced plasma, is useful for the treatment and control of bleeding associated with fibrinogen deficiency.

GRANULOCYTE TRANSFUSIONS

Granulocytes are sometimes transfused in neutropenic patients with life-threatening infections (Chapters 153 and 260). However, their benefit in such patients is unproven.[A6]

INDICATIONS FOR COMPONENT MODIFICATION

LEUKOREDUCTION

The majority of RBC and platelet products are leukoreduced prior to storage. Leukoreduction removes white blood cells from the unit to mitigate febrile nonhemolytic transfusion reactions, HLA alloimmunization, CMV transmission, and transfusion-related immunomodulation. Thus, leukoreduction is indicated in patients at risk for these complications, such as potential transplant patients, patients with a history of febrile nonhemolytic transfusion reactions, pregnant patients, and immunocompromised patients.

CYTOMEGALOVIRUS SERONEGATIVE

For the mitigation of transfusion-transmitted cytomegalovirus, patients at risk for cytomegalovirus disease should receive leukoreduced, cytomegalovirus seronegative,[A7] or pathogen-reduced blood components. Such at-risk patients include transplant candidates, transplant recipients, patients undergoing chemotherapy, pregnant women, and immunocompromised patients.

IRRADIATION

Irradiation or pathogen reduction, which inactivates white blood cells so they cannot replicate, is used to prevent transfusion-associated graft-versus-host disease. Indications for irradiation include congenital immunodeficiency; stem cell transplantation; Hodgkin disease; use of purine analogue drugs, anti-CD32, or other drugs that alter T-lymphocyte function; intrauterine transfusion; neonatal exchange transfusion; leukemia; lymphoma; intense chemotherapy; congenital heart disease (DiGeorge syndrome); and aplastic anemia. Products from blood relatives, HLA match products, and granulocyte products should be irradiated.

PATHOGEN REDUCTION

Pathogen reduction mitigates the need for irradiation, cytomegalovirus seronegative blood products, testing for *Babesia*, and bacterial screening. Currently, this technology is mostly used in platelets and plasma. For plasma, solvent/detergent treated, pooled plasma product, or pathogen-reduced plasma product is available. The incidence of transfusion-related acute lung injury and allergic reactions with solvent detergent-treated pooled plasma is much lower than the risk with other plasma products.

For pathogen-reduced platelets data show: uncertainty as to whether pathogen-reduced platelets increase the risk of any bleeding, no evidence of difference in the incidence of clinically significant bleeding complications, probably no difference in all-cause mortality, probably no difference in serious adverse events, an increased risk of developing platelet refractoriness, an increased requirement for platelet transfusions, a shorter time interval between transfusions, and lower corrected platelet count increment compared with standard platelets.[A8]

SPECIFIC CLINICAL SETTINGS

Perioperative Alternatives to Allogeneic Transfusion

Autologous Donations

Patients may donate their own blood in the weeks prior to elective surgery. The advantages of such "preoperative autologous donation" include decreased risk of infectious disease transmission, decreased risk of alloimmunization to donor antigens, and the ready availability of compatible blood products if the patient requires rare RBC components. Its disadvantages include additional cost, potential adverse reactions associated with autologous blood donation, and the development of iatrogenic preoperative anemia associated with phlebotomy. These components are more expensive than allogeneic components because they are specially handled to ensure that they are transfused only to the intended recipient. Further concerns include bacterial contamination, transfusion-associated circulatory overload, and the potential for mislabeling. Additionally, the wastage rate for autologous components is about 60%, thereby suggesting that most autologous donations are unnecessary. As a result, routine use of autologous components is not recommended.

Directed Donors

Individuals who donate blood components for use by a specific patient, typically a family member or friend, are referred to as "directed donors." Although directed donors are typically motivated by compassion for the patient, components from directed donations are not safer than components from volunteer donations. Directed donors may intentionally or unintentionally omit information that might otherwise preclude them from donating, and this omission may compromise the safety of the resulting product. Nevertheless, directed donations from relatives may be medically desirable when a patient requires HLA-matched components or RBCs with a rare phenotype. All directed donations from blood relatives should be irradiated to prevent transfusion-associated-graft-versus-host disease.

Reinfusion of Recovered Blood

To salvage and reinfuse blood lost during a surgical procedure, intraoperative blood recovery is an option. The simplest approach is direct reinfusion of recovered blood without washing. In this method, recovered blood is collected, anticoagulant is added, and blood is reinfused. Recovered blood also can be washed with saline prior to reinfusion. Blood recovered by these methods must be reinfused within 4 hours or, if stored at 1° to 6° C, within 24 hours of the start of collection.

Cell salvage can be set up to meet the needs of patients who refuse blood transfusion, such as some Jehovah Witnesses. Potential contraindications to intraoperative blood recovery include a contaminated surgical site, blood collected from surgical procedures for cancer with the potential risk of tumor cell contamination, and blood collected in surgical sites that contain medications.

In the process of acute normovolemic hemodilution, intraoperative removal of whole blood into standard collection bags is replaced simultaneously with crystalloid or colloid of equal volume. Hemodilution reduces RBC loss because a bleeding patient with an iatrogenically lowered hematocrit loses fewer RBCs. The removed whole blood is stored in the operating room and reinfused in reverse order of collection. This approach allows for the components with the highest hematocrit to be transfused last, presumably when surgical bleeding has been controlled. The whole blood also has functioning platelets and coagulation factors. The iatrogenic anemia can compromise oxygen transport, but this problem is usually mitigated by the decrease in blood viscosity. If kept at room temperature, the collected components must be used within 8 hours of collection; if stored at 1° to 6° C, they must be used within 24 hours of collection.

Most patients tolerate the transfusion of autologous blood collected postoperatively from draining serosal cavities. Adverse effects can include respiratory distress, hypotension with anaphylaxis, and fever. Blood collected postoperatively must be used within 6 hours of collection.

MASSIVE TRANSFUSION

Massive transfusion is defined as transfusion of 10 or more RBC components (units) within 24 hours. Other definitions of massive transfusion include replacement of 50% of total blood volume within 3 hours or blood loss exceeding 150 mL per minute. Current practice is for a 1 : 1 : 1 or 1 : 1 : 2 ratio of plasma : platelets : RBCs during massive transfusion. In patients with severe trauma, a 1 : 1 : 1 ratio can reduce the rate of exsanguination within 24 hours and provide better hemostasis compared with a 1 : 1 : 2 ratio, but overall rates of complications and mortality are no different at 24 hours and 30 days.[A9] As a result, the 1 : 1 : 2 ratio remains the most commonly recommended transfusion ratio. Other options include the use of whole blood,[17] tranexamic acid, and the decision to transfuse guided by thromboelastography to assess clotting under expert supervision. Randomized trials have demonstrated improved survival with prehospital plasma transfusion when transport times are longer than 20 minutes.[A10]

HEMOGLOBINOPATHIES

Patients with hemoglobinopathies, such as thalassemia (Chapter 148) and sickle cell disease (Chapter 149), often require chronic transfusion. Patients who have sickle cell disease are at especially high risk of forming alloantibodies.

The use of prophylactic antigen matching has decreased alloimmunization rates from about 50% to 10% with limited matching (D, C, E, K antigens) and 5% with extended matching (D, C, E, K, Jk^b, Fy^a antigens). Additionally, individuals of African descent have variant Rh genes so may phenotype as positive but make alloantibodies to the antigen. As a result, genotyping for RBC antigens in this population is helpful to determine the appropriate antigen-negative component product. Providing units based on the patient's genotype has increased post-transfusion hemoglobin levels and transfusion intervals. Lastly, RBC units for sickle cell patients are hemoglobin S negative and labeled as such.

Patients with thalassemia (Chapter 148) may require chronic lifelong transfusion as frequently as every 2 to 5 weeks to maintain pretransfusion hemoglobin levels above 9 to 10.5 g/dL in order to promote normal growth and physical activity and suppress bone marrow activity. The predominant transfusion complication in these patients is iron overload.

PATIENT BLOOD MANAGEMENT

The goals of a patient blood management program include increasing awareness of evidence-based transfusion guidelines, reducing the likelihood of a transfusion, minimizing blood loss, improving blood utilization, continuously educating clinicians, and standardizing metrics. Implementation of patient blood management programs have decreased blood utilization, decreased cost, and improved patient care. Optimizing RBC mass includes the preoperative evaluation of anemia, the timing of surgery, and the optimization of postoperative erythropoiesis. Minimizing blood loss includes management of the risk of bleeding, meticulous surgical technique, blood sparing devices, blood conservation strategies, maintenance of normothermia, use of hemostatic agents, monitoring for postoperative bleeding, blood salvage, minimizing iatrogenic blood loss, managing anticoagulation, and prophylaxis for gastrointestinal hemorrhage. Optimizing physiologic anemia reserve includes estimating blood loss compared with the patient's tolerance, formulating a patient-specific blood management plan, optimizing cardiac output and oxygenation, optimizing anemia reserve, maximizing oxygen delivery, minimizing oxygen consumption, avoiding and treating infections, and using restrictive transfusion thresholds.

To decrease unnecessary use of blood products, general principles include:[18,19]

1. Do not transfuse more units than necessary. Transfuse using a restrictive threshold. Consider transfusing a single unit of RBCs in stable, nonbleeding hospitalized patients, and then checking the patient's hemoglobin and clinical status prior to further transfusions.
2. Do not proceed with elective surgery prior to evaluating and treating anemia.
3. Do not transfuse RBCs for iron deficiency if patients are hemodynamically stable. Iron-deficient patients should receive oral or intravenous iron.
4. Do not use blood products to reverse warfarin. Patients can generally be reversed with vitamin K alone. Prothrombin complex concentrates should be used in the setting of serious bleeding or the need for emergent surgery. Do not transfuse plasma to correct a mildly elevated INR (<1.8).
5. Do not perform serial blood counts on clinically stable patients. Repeat blood draws can result in iatrogenic anemia.
6. Do not transfuse O-negative blood except to O-negative patients and in emergencies for women of childbearing potential with unknown blood group. O-negative RBCs are in chronic short supply and should be restricted to patients who need them.
7. Do not transfuse AB plasma to non-AB patients except in emergency situations in which ABO blood type is unknown. Group A plasma can also be used for emergency transfusions.

163 HEMATOPOIETIC CELL TRANSPLANTATION

NELSON J. CHAO AND ARMAND KEATING

Hematopoietic cell transplantation is a procedure by which hematopoietic stem and progenitor cells are infused intravenously to restore hematopoiesis and immune function following a chemotherapy conditioning regimen, with or without radiation therapy, that ablates the endogenous hematopoietic and immune system.[1] Stem cells used for hematopoietic cell transplantation are of hematopoietic origin, in contrast to the more primitive pluripotent stem cells (i.e., embryonic stem cells) that are considered for regenerative therapy because of their ability to differentiate into virtually any somatic cell. Hematopoietic cell transplantation is now a standard treatment for many hematologic malignancies, immunodeficiency states, enzyme deficiencies (e.g., Hurler syndrome [Chapter 192]), and defective hematopoietic states (e.g., severe aplastic anemia [Chapter 151]).[2] In addition, hematopoietic cell transplantation can also treat hemoglobinopathies, immune deficiency states, and selected autoimmune diseases.[3] The infused hematopoietic stem/progenitor cells can give rise to all blood elements, including cells of the immune system, and they may be genetically modified to enhance their function. Furthermore, hematopoietic stem/progenitor cells may be manipulated ex vivo and used in the burgeoning field of regenerative medicine. Taken together, hematopoietic cell transplantation is a major component and foundation of the broader field of cellular therapy (Chapter 34).

The three cell sources for hematopoietic cell transplantation are syngeneic (i.e., cells from an identical twin), allogeneic (i.e., cells from a nonidentical donor), and autologous (i.e., reinfusion of one's own cells). The determination of the type of hematopoietic cell transplantation that a patient receives is based on the disease to be treated, the disease state (e.g., initial treatment vs. treatment of recurrent disease), the urgency with which the disease needs to be treated, the availability of a donor, and the time necessary to obtain hematopoietic stem/progenitor cells from a donor.

Hematopoietic stem/progenitor cells may be obtained from bone marrow (by serial aspirations from the posterior iliac crests while the donor is under general anesthesia), peripheral blood (after stimulation with hematopoietic growth factors such as granulocyte colony–stimulating factor [G-CSF] or plerixafor [a CXCR4 antagonist], followed by leukapheresis), or umbilical cord blood. In current practice, peripheral blood is the source for hematopoietic stem/progenitor cells in approximately 90% of autologous transplants and in approximately 70% of allogeneic transplants because of the relative ease of procurement and the donor's rate of hematopoietic recovery after infusion compared with cells derived from bone marrow.

Hematopoietic stem/progenitor cells may be infused fresh or after cryopreservation, which involves processing the cells in culture medium containing

ABSTRACT

Hematopoietic cell transplantation is a procedure by which hematopoietic stem and progenitor cells are infused intravenously to restore hematopoiesis and immune function following a chemotherapy conditioning regimen, with or without radiation therapy, that ablates the endogenous hematopoietic and immune system. Stem/progenitor cells can be collected from a variety of sources, including bone marrow, peripheral blood, or umbilical cord blood.

The three types of hematopoietic cell transplantation are syngeneic (i.e., cells from an identical twin), allogeneic (i.e., cells from a nonidentical donor), and autologous (i.e., reinfusion of one's own cells). Because of better tissue typing, less intensive preparatory regimens, modern supportive measures, and expanded options for identifying qualified donors, the outcomes of hematopoietic cell transplantation have steadily improved. Hematopoietic cell transplantation is now used to treat blood cancers and other malignancies, enzyme deficiencies, hemoglobinopathies, and autoimmune disorders.

Complications associated with all forms hematopoietic cell transplantation include direct organ toxicities from the conditioning regimen as well as prolonged cytopenias that can result in infections and bleeding. Graft-versus-host disease (i.e., the donor rejecting the recipient) is a complication unique to allogeneic hematopoietic cell transplantation. Recurrence of malignancy remains the primary cause of treatment failure after both autologous and allogeneic hematopoietic cell transplantation.

dimethyl sulfoxide (DMSO), placing them in specialized plastic bags, controlled freezing, and then storing in the vapor phase of liquid nitrogen until needed. Cord blood hematopoietic stem/progenitor cells are collected at the time of delivery, cryopreserved, and stored. For allogeneic donation, cells may also be infused on the day of collection. For autologous donation, cells are almost always cryopreserved.

ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

The distinctive characteristics of allogeneic hematopoietic cell transplantation are that the stem cell graft allows for the establishment of a new immune system in addition to reconstitution of white blood cells, red blood cells, and platelets. The new immune system can be a major advantage if the immunologic response is directed against malignant cells, referred to as the graft-versus-leukemia or graft-versus-tumor effect, which potentially can eradicate disease and reduce the chance of disease relapse. However, if the immunologic response is directed against antigens present on normal tissues, the graft-versus-host response can result in the destruction of normal organs and is clinically described as graft-versus-host disease (GVHD). The risk for both graft rejection (host-versus-graft reaction) and GVHD rises with the degree of human leukocyte antigen (HLA) disparity between the donor and the recipient as well as the degree of immune suppression.

The clinical importance of the role that immunocompetent donor T cells play in mediating a graft-versus-tumor effect is exemplified by the increased rates of relapse in patients who receive allogeneic bone marrow grafts from which T cells had been removed (T-cell depletion), an inverse correlation between relapse and severity of GVHD, and increased rates of relapse after syngeneic or autologous hematopoietic cell transplantation in patients who have received similar conditioning regimens. However, the most compelling evidence for the importance of T cells mediating the graft-versus-tumor effect is the clinical observation that infusion of allogeneic T cells alone, termed a *donor lymphocyte infusion*, at a time remote from the transplant conditioning regimen can successfully eradicate leukemia that has persisted or recurred after allogeneic hematopoietic cell transplantation. Nevertheless, the clinical effectiveness of graft-versus-tumor can vary widely among different malignancies.

Because of the immunologic barriers that can result in graft rejection and GVHD, allogeneic hematopoietic cell transplantation requires that the donor and the recipient share as many key genes as possible. The most important of these are HLAs (Chapter 38), which are derived from the MHC located on chromosome 6. The HLA loci include HLA-A, HLA-B, HLA-C, DR, DP, and DQ. A single set of major histocompatibility complex (MHC) alleles, described as a haplotype, is inherited from each parent, thereby resulting in HLA pairs. A clinical "match" means that HLAs in the donor match the HLAs in the patient.

The choice of donor for an allogeneic hematopoietic cell transplantation takes into account several factors, including the patient's specific disease and disease state (i.e., remission vs. relapse) and the time that is required for obtaining hematopoietic stem/progenitor cells from a donor. A fully HLA-matched sibling is the preferred donor source because the risks for graft rejection and GVHD are lowest. The probability of having an HLA match with a single sibling is 25% and increases with the number of siblings within a specific family. This probability can be estimated using the following formula: chance of having an HLA-matched sibling $= 1 - (0.75)^n$, where n is the number of potential sibling donors. There is approximately a 1% chance of a crossover event (i.e., genetic material switched between chromosomes during meiosis), primarily between the HLA-A and the HLA-B loci. The clinical outcomes for allogeneic hematopoietic cell transplantation using a sibling with a single HLA mismatch are similar to those with a fully HLA-matched sibling.

For patients who lack an HLA-identical sibling donor, the alternative sources for allogeneic hematopoietic stem/progenitor cells include a fully HLA-matched volunteer unrelated donor, a fully or partially HLA-matched cord blood unit, or a partially HLA-matched first-degree family member. HLA genes are highly polymorphic, so the odds that any two unrelated individuals are HLA identical for main loci are less than 1 in 10,000. However, tens of millions of people worldwide are currently listed as potential volunteer donors, so a donor can be found for about 50% of all patients for whom a search is initiated. The probability of identifying a suitable volunteer donor is highly dependent on race because of varying degrees of HLA diversity. For example, for persons of northern European extraction, the probability of a match can be as high as 90%. In contrast, minority populations may have less than a 20% probability of a match because of fewer volunteer donors and a higher degree of genetic variation.

It usually takes about 2 to 4 months to locate and fully evaluate an unrelated donor, which may be too long for some patients with rapidly progressive malignancies. When a suitable volunteer is not available or a donor is needed more urgently, alternative sources can be considered, including partially HLA-matched ("haploidentical") relatives or umbilical cord blood. Haploidentical hematopoietic stem/progenitor cells are readily available but have increased risks for graft rejection and GVHD. These risks can be reduced by either ex vivo or in vivo T-cell depletion methods, but T-cell depletion may lead to delayed immune reconstitution and competency after transplantation, thereby increasing the risks for infection and recurrent disease. However, post-transplantation cyclophosphamide for GVHD prophylaxis has markedly increased the clinical use of haploidentical donors.

Umbilical cord blood hematopoietic stem/progenitor cells, which are taken at the time of delivery and stored in cord blood banks, are readily available within 2 to 4 weeks when needed. Because of the unique immature biology of lymphocytes in umbilical cord blood, these transplants are associated with less GVHD; consequently, the HLA-matching requirements are less strict, and two or three HLA mismatches may be acceptable. However, the small volume (50 to 150 mL) of cord blood that can be collected limits the number of hematopoietic stem/progenitor cells and often prohibits their use in adults because successful engraftment correlates with the number of cells per patient body weight. The limitation of cell dose can be overcome by the use of more than one cord blood unit and the ability to expand cord blood cells ex vivo, thereby resulting in engraftment rates similar to other cell sources. One significant disadvantage is that the use of a cord blood unit eliminates the probability of obtaining additional cells if the graft fails or if a donor lymphocyte infusion is required.

After a source of allogeneic stem cells has been identified, patients then receive a pretransplant regimen with the intent of "conditioning" or "preparing" them for the infusion (Fig. 163-1). These conditioning regimens are designed to be adequately immunosuppressive to overcome the host-versus-graft reaction and permit engraftment. They also are designed to eradicate the primary tumor in patients with an underlying malignancy. Most conditioning regimens use chemotherapy alone or a combination of total body irradiation or total nodal irradiation with chemotherapy. The doses of total body and total lymphoid irradiation vary between 200 and 1440 cGy. The most commonly used chemotherapy for conditioning regimens is an alkylating agent (e.g., cyclophosphamide, busulfan, thiotepa) combined with immunosuppressive drugs such as fludarabine. Conditioning regimens also may contain monoclonal antibodies that target T cells (e.g., antithymocyte globulin, alemtuzumab).

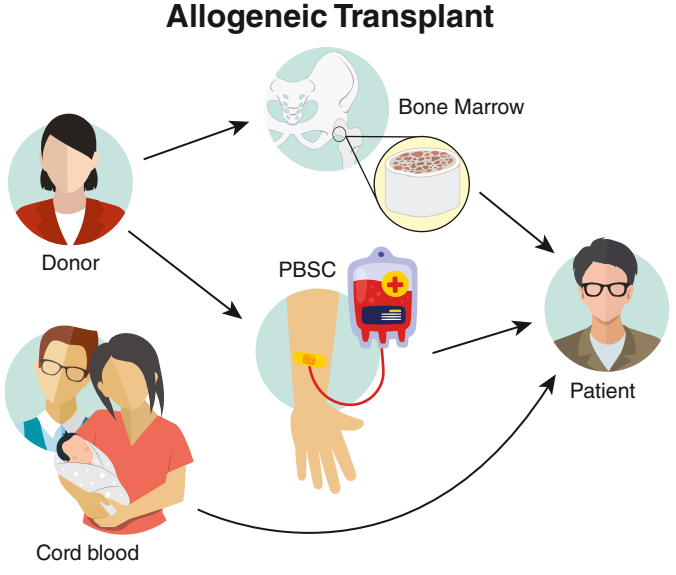

FIGURE 163-1. The process of allogeneic hematopoietic cell transplantation. (1) The patient receives a conditioning regimen of chemotherapy and/or radiation therapy that is used to both eliminate the underlying malignancy and suppress the immune system to prevent rejection of the allogeneic hematopoietic stem cells. (2) Allogeneic hematopoietic stem cells are then collected directly from the bone marrow or from the blood of a related or unrelated stem cell donor and infused intravenously into the donor. (3) After the infusion of the hematopoietic stem cells, the patient receives immunosuppressant drugs to help prevent the development of graft-versus-host disease (GVHD). PBSC = peripheral blood stem cells. (Image courtesy of the National Marrow Donor Program.)

The choice of a specific conditioning regimen depends on the disease being treated, and the doses of chemotherapy and radiation are highly variable. When the doses result in a degree of myelosuppression and immunosuppression that is nearly universally fatal without the infusion of hematopoietic stem/progenitor cells as a rescue product, they are referred to as myeloablative.

Allogeneic hematopoietic cell transplantation with myeloablative conditioning regimens has been performed successfully in patients older than age 60 years, but survival after transplantations declines with increasing age, thereby limiting the application of allogeneic transplantation to a minority of patients who potentially could benefit from this procedure. However, the demonstration that an immune-mediated graft-versus-tumor effect plays a central role in the therapeutic efficacy of allogeneic hematopoietic cell transplantation led to the development of less intensive conditioning regimens that are adequately immunosuppressive to permit the engraftment of donor cells but associated with decreased toxicities compared with myeloablative regimens. Another advantage of less intensive conditioning is that it can be delivered outside of the hospital setting, so that patients receive their care in the outpatient setting and are able to stay in a local apartment or their actual home if they live close to the center. Although the reduced doses of radiation and chemotherapy result in decreased antitumor activity and are associated with higher rates of recurrent disease after transplantation, these "nonmyeloablative" and "reduced-intensity" conditioning regimens have markedly increased the potential option of allogeneic hematopoietic cell transplantation for older patients and patients with preexisting comorbidities.

SYNGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

The major advantage of a syngeneic hematopoietic cell transplantation from an identical twin is that it is not associated with GVHD or graft rejection, thereby resulting in a relatively low risk for treatment-related morbidity and mortality. Syngeneic hematopoietic cell transplantation, as with allogeneic transplantation, also avoids potential contamination with malignant cells. The major disadvantage of syngeneic transplantation is that it does not provide the graft-versus-leukemia effect associated with allogeneic transplantation. However, since far less than 1% of patients have an identical twin, syngeneic transplantation is rarely an option.

AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION

The major rationale for autologous hematopoietic cell transplantation with the patient's own cells is that certain malignancies, such as leukemias and lymphomas, have a steep dose-response curve to chemotherapy and, to a relative degree, radiation. However, the associated limitation of higher doses of chemotherapy or radiation attenuates myelosuppressive effect. The infusion of autologous hematopoietic stem/progenitor cells (and for that matter, allogeneic and syngeneic cells) can restore hematopoiesis after the prior administration of high-dose chemotherapy, with or without radiation. The major advantages of autologous as compared with allogeneic transplantation are that the patient can serve as his or her own donor and that it may be performed in older patients with significantly lower morbidity and mortality because of the absence of GVHD. Although patients undergoing autologous hematopoietic cell transplantation have higher relapse rates than patients undergoing allogeneic transplantation, the lower rates of other complications seem to translate into similar long-term outcomes. Nevertheless, the higher conditioning doses of chemotherapy before autologous hematopoietic cell transplantation can be associated with more morbidity than conventional doses of chemotherapy.

INDICATIONS FOR TRANSPLANTATION

An estimated 90,000 hematopoietic cell transplantations are performed annually worldwide, primarily for the treatment of hematologic malignancies, bone marrow failure states, and immune and enzyme deficiencies (Fig. 163-2).

Acute Myeloid Leukemia

Allogeneic hematopoietic cell transplantation is capable of resulting in the long-term survival of 10% of patients with otherwise refractory acute myeloid leukemia (AML; Chapter 168).[4] By comparison, cure rates of 40 to 70% have been reported with hematopoietic cell transplantation performed during a first complete remission, and rates of 20 to 40% have been achieved in patients treated while in a second or subsequent complete remission. In randomized trials of patients with AML in first complete remission, both autologous and allogeneic hematopoietic cell transplantation provide improved leukemia-free survival compared with conventional chemotherapy. In terms of overall survival, however, meta-analyses demonstrate improvement with allogeneic hematopoietic cell transplantation compared with nonallogeneic treatments for AML in first complete remission in patients who have intermediate- and high-risk cytogenetics but not in patients who have good-risk AML.[A1] Data also indicate the importance of molecular mutations. For example, intermediate-risk AML with a normal karyotype represents a highly heterogeneous group with respect to prognosis based on molecular mutation status. Approximately one third of patients with normal-karyotype AML harbor the *FLT3*-internal tandem mutation, which carries a poor prognosis and may benefit from HLA-matched related hematopoietic cell transplantation, regardless of the presence of other mutations.

Acute Lymphoblastic Leukemia

Conventional chemotherapy provides excellent outcomes for childhood acute lymphoblastic leukemia (ALL), except for ALL associated with the Philadelphia chromosome (Chapter 168). In adults, however, remission, though frequently attained after intensive induction therapy, is commonly followed by relapse. Adverse prognostic factors include the presence of the Philadelphia chromosome, a high white blood cell count, advancing age, and the presence of minimal residual disease. Studies suggest that consolidation therapy including hematopoietic cell transplantation after initial chemotherapy improves overall survival compared with conventional chemotherapy alone, particularly for those who are Philadelphia chromosome–positive. For both pediatric and adult patients with relapsed ALL, the overall prognosis is relatively poor, and the general treatment strategy is to obtain a second complete remission and then proceed to an allogeneic hematopoietic cell transplantation.

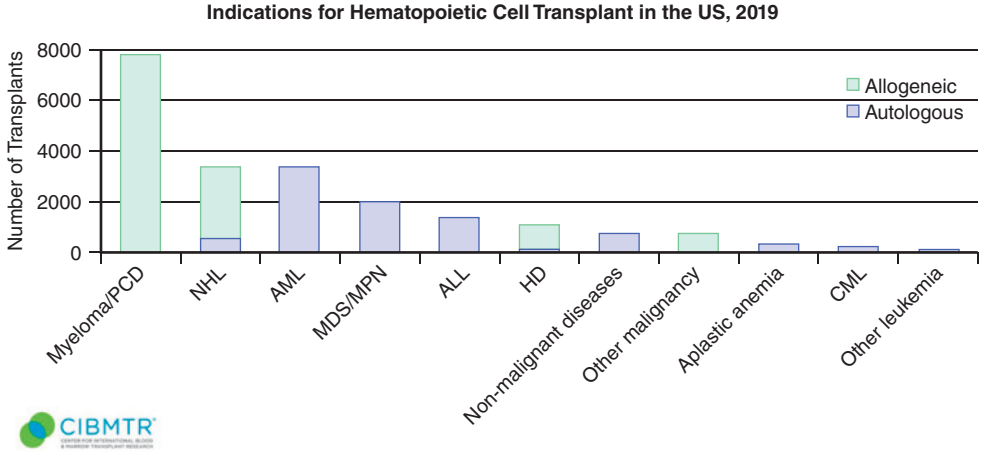

FIGURE 163-2. Indications for hematopoietic cell transplantation in the United States as reported to the Center for International Blood and Marrow Transplant Research. ALL = acute lymphocytic leukemia; AML = acute myeloid leukemia; CML = chronic myelogenous leukemia; HD = Hodgkin disease; MDS/MPN = myelodysplastic syndrome/myeloproliferative neoplasms; NHL = non-Hodgkin lymphoma. (Courtesy of the Center for International Blood and Marrow Transplant Research.)

Myelodysplastic Syndrome

The only known curative treatment for myelodysplastic syndrome (Chapter 167) is allogeneic hematopoietic cell transplantation. Unfortunately, the vast majority of patients are not considered candidates for this therapy for many reasons, including advanced age (the median age at diagnosis is in the seventh to eighth decade of life), comorbid diseases, the inability to identify a suitable donor, and the patient's preferences. The best results have been obtained in younger patients, who are earlier in their disease course and have not received any prior therapy. Increasing evidence suggests that reduced-intensity allogeneic hematopoietic cell transplantation may benefit even considerably older patients with myelodysplastic syndrome. A randomized trial of patients with myelodysplastic syndrome or secondary AML showed that a busulfan-based reduced-intensity conditioning regimen resulted in at least a 2-year relapse-free and overall survival, similar to that after a myeloablative conditioning regimen for allogeneic stem cell transplantation.[A2]

Chronic Myeloid Leukemia

In patients with chronic myeloid leukemia (CML; Chapter 170), hematopoietic cell transplantation is reserved for patients who are resistant to or intolerant of treatment with tyrosine kinase inhibitors, especially those who develop an accelerated phase or blast crisis CML. Although results of allogeneic hematopoietic cell transplantation are poor for accelerated-phase or blast-crisis disease, some patients may respond to tyrosine kinase inhibitors after transplantation.

Myeloproliferative Neoplasms

Myeloproliferative neoplasms, such as primary myelofibrosis, polycythemia vera, and essential thrombocythemia (Chapter 152), usually are chronic in nature but can progress to a "spent" phase and evolve into myeloid metaplasia, which is characterized by bone marrow fibrosis and a generally poor prognosis with transformation into acute leukemia and a median survival of less than 3 years. Conventional treatment options are limited at this stage, and the accepted standard of care for myeloid metaplasia/myelofibrosis is allogeneic hematopoietic cell transplantation, especially nonmyeloablative transplantation because of the older age of most patients with this condition.

Non-Hodgkin Lymphoma

Syngeneic, allogeneic, and autologous hematopoietic cell transplantation have all been reported to yield long-term, disease-free survival and an apparent cure for patients with advanced non-Hodgkin lymphoma (Chapter 171). Based on its risk-benefit ratio and availability, the standard of care for patients with primary refractory or chemotherapy-sensitive relapsed non-Hodgkin lymphoma of specific histologies (including diffuse large B-cell lymphoma) has been autologous hematopoietic cell transplantation. For mantle cell lymphoma, autologous hematopoietic cell transplantation appears to improve progression-free and possibly overall survival when used as part of front-line therapy, especially when combined with maintenance rituximab post-transplantation.[A3] The development of chimeric antigen receptor (CAR) T cells for lymphomas may challenge this sequence depending on the results of ongoing trials.

However, the graft-versus-tumor effect against various non-Hodgkin lymphoma histologies is very heterogeneous, and consensus is currently lacking regarding for which histology allogeneic hematopoietic cell transplantation is appropriate. For example, autologous transplantation can result in disease-free survival rates as high as 60% in patients with indolent follicular non-Hodgkin lymphoma,[A4] but late relapses after transplantation and the long overall survival observed with current medical therapy have reduced the role for hematopoietic cell transplantation despite its graft-versus-tumor effects.

Hodgkin Lymphoma

Based on a small prospective randomized trial conducted in the early 1990s, autologous hematopoietic cell transplantation has become the standard of care for patients with primary refractory and relapsed Hodgkin lymphoma (Chapter 172) whose disease nevertheless remains sensitive to chemotherapy. The usual approach is first to treat these patients with second-line chemotherapy and then with high-dose chemotherapy and autologous hematopoietic cell transplantation. Allogeneic transplantation has had a limited role because of the efficacy of autologous transplantation and the significant treatment-related toxicities associated with myeloablative allogeneic transplantation, but reduced-intensity allogeneic transplantation can be an option, especially in patients who relapse after autologous transplantation.

Multiple Myeloma

Although immunomodulatory derivatives and proteasome inhibitors are highly effective for the treatment of multiple myeloma (Chapter 173), early autologous hematopoietic cell transplantation, when feasible, remains the standard of care.[5] Prospective comparisons of single versus tandem autologous transplants give conflicting results, although overall survival rates appear similar. Single-arm and randomized trials support the use of a second autologous transplantation for patients who relapse after the first autologous transplantation, provided the duration of response was more than 1 year after the initial transplantation.

Solid Tumors

High-dose chemotherapy plus transplantation has had success in the treatment of some chemotherapy-sensitive solid tumors, including germ cell tumors and childhood cancers such as neuroblastoma and Wilms tumor. In patients who have germ cell tumors that are not cured by platinum-based chemotherapy regimens, high-dose chemotherapy and autologous hematopoietic cell transplantation has resulted in prolonged disease-free survival, even in patients with refractory disease.

Nonmalignant Conditions

Allogeneic hematopoietic cell transplantation can lead to long-term, disease-free survival in more than 50% of patients with severe aplastic anemia (Chapter 151). When compared with standard immunosuppressive therapy, allogeneic transplantation is more likely to produce a complete and durable reversal of the hematologic abnormalities. Patients with aplastic anemia who are less heavily transfused have better outcomes with allogeneic transplantation. For patients with less severe aplastic anemia, patients older than 40 years, and patients without a matched sibling donor, a trial of immunosuppression therapy is usually appropriate before consideration of allogeneic transplantation (Chapter 151).

Hematopoietic cell transplantation is also an effective treatment for other nonmalignant disorders, including thalassemia (Chapter 148), sickle cell disease (Chapter 149), immunodeficiency disorders, and enzyme deficiency states, primarily in children and young adults. Hemoglobinopathies can be cured by allogeneic hematopoietic cell transplantation, but new approaches such as gene therapy and the application of the clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR-associated protein 9 (CRISPR-Cas9) system may supplant hematopoietic cell transplantation (Chapter 34).[6] In thalassemia, the best transplant results have been obtained in pediatric patients with HLA-identical sibling donors. Adults tend to have more advanced disease with greater iron overload and more organ dysfunction; hence, they have high treatment-related mortality. Studies with nonmyeloablative regimens are ongoing. There is less experience with sickle cell disease (Chapter 149), partly because of reluctance to contemplate allogeneic hematopoietic cell transplantation in patients with an unpredictably variable clinical course.

For severe autoimmune disease, including systemic lupus erythematosus, rheumatoid arthritis, scleroderma, and multiple sclerosis, hematopoietic cell transplantation can reconstitute the immune system without the patient's native autoreactive T-cell clones. Trials have demonstrated clinically significant responses in patients with severe scleroderma (Chapter 246) and advanced multiple sclerosis (Chapter 380). In adults with severe scleroderma, for example, a randomized trial of myeloablative autologous hematopoietic cell transplantation showed long-term benefits, including improved event-free and overall survival, compared with 12 monthly infusions of cyclophosphamide.[A5]

COMPLICATIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

Improved supportive measures have led to a steady improvement in the outcomes of hematopoietic cell transplantation. Early complications, which are associated with all forms of hematopoietic cell transplantation, include direct organ toxicities from the conditioning regimen (e.g., mucositis) as well as prolonged cytopenias that can predispose to infections and bleeding.[7] Allogeneic hematopoietic cell transplantation also can be associated with acute and chronic GVHD. Long-term complications, particularly secondary malignancies, require that patients continue to be monitored for the remainder of their lives. A simple tally of the number of comorbid conditions can reliably predict nonrelapse mortality and survival and is useful for counseling patients before transplantation. Blood biomarkers may also

become useful for predicting complications after transplantation, including the future occurrence of GVHD and its responsiveness to therapy, as well as nonrelapse mortality.

GRAFT-VERSUS-HOST DISEASE (GVHD)

Around the time of engraftment, patients are at risk for the development of GVHD, which represents the most important clinical challenge with allogeneic hematopoietic cell transplantation.[8] GVHD occurs when donor T cells recognize recipient antigens as foreign and attack these cells/organs. The pathophysiology involves many other cell types, cytokines, and even an important interaction with the host's microbiome, primarily the gut microbiome.[9]

GVHD can be either acute,[10] generally presenting within the first 100 days after transplantation, or chronic,[11] generally presenting after the first 100 days. However, clinical features of both acute and chronic GVHD may be observed at any time following allogeneic hematopoietic cell transplantation, and clinical manifestations rather than time after transplantation may best determine whether the GVHD syndrome is considered acute or chronic.

The incidence of clinically significant GVHD (grades II to IV) in recipients of HLA-matched sibling grafts (T-cell replete) using tacrolimus and methotrexate for GVHD prophylaxis is approximately 30 to 40%. The incidence of grades II to IV GVHD in recipients of HLA-matched unrelated donor grafts is approximately 50 to 80%.

ACUTE GRAFT-VERSUS-HOST DISEASE (GVHD)

The broad category of acute GVHD includes "classic" acute GVHD, occurring within 100 days after transplantation or donor lymphocyte infusion, as well as "persistent," "recurrent," or "late" acute GVHD, occurring beyond 100 days after transplantation or donor lymphocyte infusion. Risk factors for acute GVHD include HLA mismatch, a female donor (particularly a multiparous donor), more advanced age of the patient and the donor, cytomegalovirus seropositivity of the donor or patient, use of an unrelated donor, or use of a T-cell-replete versus T-cell-depleted graft.

CLINICAL MANIFESTATIONS

Acute GVHD primarily affects the skin, gastrointestinal tract, and liver. The skin manifestations range from a maculopapular rash to generalized erythroderma or desquamation. The severity of gastrointestinal GVHD is based on the amount of diarrhea per day and the presence of an ileus. The severity of liver GVHD is scored on the basis of the bilirubin level. Organs may be involved in isolation or simultaneously.

DIAGNOSIS

Histologic confirmation can be valuable to exclude other possibilities, such as infection. Mild GVHD of the skin may demonstrate vacuolar degeneration and infiltration of the basal layer by lymphocytes. With more advanced disease, histologic findings of necrotic dyskeratotic cells with acantholysis may progress to frank epidermolysis. In the liver, early GVHD may be difficult to distinguish from hepatitis of other causes. A clinical grading system (Table 163-1) correlates with clinical outcome.

PREVENTION

The best approach to GVHD is prevention.[12] The prophylactic use of cyclosporine plus methotrexate is equivalent to the combination of tacrolimus plus sirolimus in terms of reducing the incidence and severity of acute GVHD and improving survival after allogeneic cell transplantation.[A6] In a nonrandomized study, the addition of sitagliptin, which inhibits dipeptidyl peptidase 4, reduced acute GVHD from its usual 30 to 40% incidence rate to less than 10%.[13]

Cyclosporine has significant toxicities, including hypertension, nephrotoxicity, hypomagnesemia, risk for seizures, hypertrichosis, gingival hyperplasia, tremors, and anorexia. Tacrolimus closely resembles cyclosporine in mechanism of action, spectrum of toxicities, and pharmacologic interactions. For allogeneic hematopoietic cell transplantation, prophylactic immunosuppression is not lifelong; when immunologic tolerance is established, immunosuppressive agents can be slowly withdrawn and discontinued.

Another strategy to prevent GVHD is to deplete the donor's T cells from the graft. The disadvantage of this approach is its association with increased rates of relapsed disease and infection. Furthermore, overall survival does not seem to be improved.

TABLE 163-1 CLASSIFICATION OF PATIENTS WITH ACUTE GRAFT-VERSUS-HOST DISEASE

	CLINICAL STAGING		
STAGE	**SKIN**	**LIVER**	**GUT**
+	Rash <25% BSA	Total bilirubin 2-3 mg/dL	Diarrhea 500-1000 mL/day
++	Rash 25%-50% BSA	Total bilirubin 3-6 mg/dL	Diarrhea 1000-1500 mL/day
+++	Generalized erythroderma	Total bilirubin 6-15 mg/dL	Diarrhea >1500 mL/day
++++	Desquamation and bullae	Total bilirubin >15 mg/dL	Pain, with or without ileus

	CLINICAL GRADING STAGE			
GRADE	**SKIN**	**LIVER**	**GUT**	**PS**
0 (none)	0	0	0	0
I	+ to ++	0	0	0
II	+ to +++	+	+	+
III	++ to +++	++ to +++	++ to +++	++
IV	++ to ++++	++ to ++++	++ to ++++	+++

BSA = body surface area; PS = performance status.

TREATMENT

Moderate to severe GVHD (grades II to IV) requires treatment, and the mainstay of therapy is corticosteroids. Methylprednisolone (1 to 2 mg/kg/day) achieves responses in 40 to 60% of patients, and higher doses of steroids are beneficial. For steroid-refractory GVHD, oral ruxolitinib (10 mg twice daily) can provide a durable 6-month response in 90% of patients and nearly double median overall survival from 6.5 months to 11.1 months as compared with alternative therapies,[A7] such as antithymocyte globulin or various monoclonal antibodies (e.g., daclizumab, infliximab). In general, acute GVHD of the skin is most responsive to treatment, whereas GVHD of the liver is least responsive. Unfortunately, the fatality rate for steroid-refractory acute GVHD may still be as high as 50%.

CHRONIC GRAFT-VERSUS-HOST DISEASE (GVHD)

Chronic GVHD, which occurs in 20 to 50% of long-term survivors, occurs most commonly between 100 days and 2 years after transplantation and has polymorphic features similar to a number of autoimmune diseases. Chronic GVHD is classified as classic chronic GVHD, which consists only of manifestations that can be ascribed to chronic GVHD, or as acute and chronic GVDH overlap syndrome, in which features of both acute and chronic GVHD appear together. These distinctions are clinically relevant because "late-onset" acute GVHD and overlap syndrome subsets have been associated with poor survival.

Chronic GVHD is most likely to develop in older patients who also had acute GVHD or received peripheral blood rather than bone marrow grafts. In 20% of cases of chronic GVHD, however, there is no history of prior acute GVHD.

CLINICAL MANIFESTATIONS

Common manifestations include the sicca syndrome (Chapter 247); lichen planus–like skin rash; scleroderma-like skin changes (Chapter 246);[14] esophageal, intestinal, and vaginal fibrosis; obstructive lung disease with or without pneumonitis; and an elevated alkaline phosphatase level with or without hyperbilirubinemia. Underlying immunologic deficiencies, including hypogammaglobulinemia, are common and place patients at increased risk for infectious events. Adverse prognostic factors include thrombocytopenia, a progressive clinical presentation, extensive skin involvement, and an elevated bilirubin level.

DIAGNOSIS

Historically, chronic GVHD has been considered as limited, with localized skin involvement and minimal or no liver involvement, or extensive, with generalized skin involvement with or without other organ involvement. Chronic GVHD is usually a clinical diagnosis although biopsy is sometimes needed. The severity of GVHD can be graded in transplant centers based on the severity of disease for each affected organ/site at any given time.

TREATMENT

Treatment of chronic GVHD, which is guided by the extent of disease, should be initiated before patients develop functional impairment. Treatment usually begins with corticosteroids (e.g., prednisone 0.5 to 1 mg/kg/day). Ruxolitinib (10 mg twice daily) can prolong median failure-free survival from about 6 months to more than 18 months in glucocorticoid-refractory disease.[A8] Belumosudil (200 mg daily) is another potential option with an overall response rate of about 75%.[15] Ibrutinib (420 mg twice daily)[16] and pomalidomide (0.5 to 2 mg daily)[A9] are other alternatives.[17] Ibrutinib is also useful for glucocorticoid-refractory chronic GVHD. Other potential therapies include extracorporeal photopheresis, cyclosporine, ultraviolet light treatments, monoclonal antibodies, and methotrexate. Given that the most common cause of death in patients with chronic GVHD remains infection, all patients with GVHD should receive prophylactic antibiotics (penicillin 500 mg twice daily) for encapsulated bacteria, with or without intravenous immunoglobulin, depending on serum levels.

Graft Rejection

Graft rejection occurs when immunologically competent cells of host origin destroy the transplanted cells of donor origin. This complication occurs more commonly in patients who receive transplants from alternative source such as cord blood or HLA-mismatched donors, in T-cell-depleted transplants, and in patients with aplastic anemia. Graft rejection also occurs if the conditioning regimen is not sufficiently immunosuppressive to facilitate engraftment of donor cells.

Infections

Infections are a major cause of morbidity and mortality after all forms of hematopoietic cell transplantation but especially following allogeneic transplantation (Chapter 260) because of prolonged use of immunosuppression for the prevention or treatment of GVHD.[18] Bacterial infections are frequently related to central venous catheters.

Among fungal infections, candida (Chapter 310) and aspergillus (Chapter 311) infections typically occur in patients receiving prolonged high-dose corticosteroids for the treatment of GVHD. In such patients, prophylactic antifungal treatment (e.g., fluconazole 400 mg daily) and anti–*Pneumocystis jirovecii* (e.g., one double strength trimethoprim-sulfamethoxazole tablet daily) is necessary.[19]

Viral infections include reactivation of cytomegalovirus (Chapter 347), human herpesvirus 6, BK virus (Chapter 341), and Epstein-Barr virus (Chapter 348) infections. Letermovir prophylaxis (480 mg orally daily through day 100) can significantly reduce the risk of cytomegalovirus reactivation.[A10] Varicella zoster vaccination (Chapter 346) can significantly reduce zoster reactivation[A11] in post-transplantation patients, but the live vaccine should not be used. These patients are also susceptible to seasonal respiratory viruses. Influenza vaccination (Chapter 332) and revaccination for common childhood infections (Chapter 15) are required after transplantation.[20] Vaccines for COVID-19 are recommended once blood counts and CD4 counts have recovered.

Cardiac Toxicity

Most transplant centers screen potential patients for underlying cardiac abnormalities that would place them at a potentially increased risk during the procedure. Despite this screening, however, a small number of patients experience a cardiac arrhythmia (Chapters 51 to 53), heart failure (Chapters 45 and 46), or cardiac ischemia (Chapter 57), either acutely during the transplantation or at a later time, often due to the large volumes of fluids administered during the procedure or from the added physiologic stress. A pericardial effusion (Chapter 62) can develop during or after transplantation, especially in patients with initial disease or radiation therapy near that area. An idiosyncratic cardiomyopathy, associated with the administration of high doses of cyclophosphamide, has been documented in a small number of patients. Viral cardiomyopathies (Chapter 47) also can be seen.

Engraftment Syndrome

Engraftment syndrome occurs when the neutrophil count recovers after either autologous or allogeneic hematopoietic cell transplantation. Engraftment syndrome consists of a constellation of symptoms and signs that may include fever, erythrodermatous skin rash, and noncardiogenic pulmonary edema. In its most extreme forms, patients also develop acute renal failure and diffuse alveolar hemorrhage. These clinical findings reflect the manifestations of increased capillary permeability and extensive release of cytokines. Corticosteroid therapy (typically prednisone at 0.5 mg/kg) is often dramatically effective for engraftment syndrome, particularly for its pulmonary manifestations.

Pulmonary Toxicities

Pulmonary toxicities are common during and after transplantation. Patients who receive certain chemotherapeutic agents, such as 1,3-bis (2-chloroethyl)-1-nitrosourea (BCNU; carmustine) have an increased incidence of chemotherapy-induced lung tissue damage, which usually occurs several weeks after transplantation and can be treated successfully with the prompt initiation of corticosteroid therapy (e.g., prednisone 1 mg/kg, with tapering initiated after response is achieved, usually within 2 weeks). In addition to these complications, patients who are undergoing allogeneic hematopoietic cell transplantation are at increased risk for pneumonitis, caused by cytomegalovirus (Chapter 347) and fungal infections, because of the patient's increased immunosuppression, and idiopathic adult respiratory distress syndrome (Chapter 90) or interstitial pneumonia (Chapter 80). Chronic GVHD also can manifest as bronchiolitis obliterans in the lung.

Liver Toxicity

The most common liver complication associated with transplantation is veno-occlusive disease/sinusoidal obstruction syndrome of the liver (Chapter 136). Symptoms associated with these complications include jaundice, tender hepatomegaly, ascites, and weight gain. Progressive hepatic and multiorgan system failure can develop in the most severe cases. Predisposing factors appear to be previous hepatic injury, use of estrogens, and high-dose intensity conditioning. Defibrotide (6.25 mg/kg every 6 hours for a minimum of 21 days) is approved by the FDA to treat advanced veno-occlusive disease in the setting of hematopoietic stem cell transplantation.

Renal Toxicity

Acute renal failure requiring dialysis occurs infrequently during transplantation, although patients with underlying renal dysfunction are at risk for this complication. An idiopathic or cyclosporine-induced hemolytic-uremic syndrome (Chapter 158) can be seen after allogeneic transplantation, can result in end-stage renal disease, and poses a high risk of mortality. Thrombotic microangiopathy also can lead to acute renal injury. Nephrotic syndrome and membranous nephropathy (Chapter 107) have been described in long-term survivors; these complications seem to be associated more commonly with chronic GVHD and nonmyeloablative conditioning.

Secondary Malignancies

One complication of chemotherapy, radiation therapy (especially total body radiation), or both used to treat malignancy and condition patients for hematopoietic cell transplantation is the development of a secondary malignancy. Secondary AML or myelodysplastic syndrome can occur after autologous transplantation. After allogeneic transplantation, the overall incidences of secondary malignancies are 2.2% at 10 years and 6.7% at 15 years. Solid malignancies occur in up to 15% of patients 15 years after hematopoietic cell transplantation with myeloablative conditioning, with no plateau in the incidence rates.[21] Within the first 1 to 2 years, the most common malignancies are Epstein-Barr virus–related lymphoproliferative disorders (Chapter 348)[22]; solid tumors are more likely to occur more than 3 years after transplantation. Risk factors include the use of antithymocyte globulin to treat GVHD, the use of a T-cell-depleted allogeneic graft, HLA incompatibility, and perhaps total body radiation. This high incidence stresses the importance of careful long-term follow-up.

Infertility and Hypogonadism

Many of the preparative regimens used for transplantation are associated with a high incidence of permanent sterility, especially regimens containing total body radiation. However, successful pregnancies have occurred in some patients after other regimens, particularly in younger patients. A reproductive endocrinologist should be consulted before transplantation when future fertility is important. Gynecomastia occasionally occurs in males.

Endocrine Dysfunction

Iatrogenic Cushing syndrome (Chapters 204 and 208) and diabetes (Chapter 210) can occur and are commonly due to long-term corticosteroid therapy for chronic GVHD. Particularly disabling are steroid-induced myopathy (Chapter 28), avascular necrosis of the hip (Chapter 229), and osteoporosis (Chapter 225). Because many patients take corticosteroids for many months, tapering can be associated with malaise, nausea, hypotension, and musculoskeletal pains. In these situations, slower tapering over several months or reintroduction of physiologic replacement doses (e.g., 7.5 to 10 mg/day of prednisone) is appropriate. Hypothyroidism (Chapter 207) is typically related to the use

of total body radiation or local radiation to the head and neck for lymphoma or other cancer.

Osteoporosis occurs in 50 to 60% of patients after hematopoietic cell transplantation. The major contributing causes include hypogonadism, secondary hyperparathyroidism caused by low serum calcium levels, and post-transplantation corticosteroid therapy. Bone mineral density should be evaluated before and after transplantation; osteopenia should be treated as appropriate with bisphosphonates, calcium, vitamin D, estrogen, and testosterone (Chapter 225).

FUTURE DIRECTIONS

There has been much progress in increasing the efficacy and safety of hematopoietic cell transplantation and in expanding the application of this treatment to more patients.[23] Areas currently under development that may further improve the use and efficacy of transplantation include continuous improvements in supportive care for transplant patients and the broadened use of alternative donors. Recurrence of disease remains the primary cause of treatment failure after both autologous and allogeneic hematopoietic cell transplantation in malignant diseases.[24] Better treatments are necessary for the treatment of GVHD and innovative studies are ongoing. Future progress depends on the ability to identify safer and better-targeted antitumor therapies that can be incorporated into transplantation regimens or given as maintenance therapy without increasing toxicity or attenuating graft-versus-tumor responses. Novel cellular therapies, including genetic modification of lymphocytes to enhance cancer-killing activity, such as chimeric antigen receptor (CAR) T cells (Chapter 34), hold considerable promise.

164 APPROACH TO THE PATIENT WITH CANCER

JAMES H. DOROSHOW

INTRODUCTION TO THE CANCER PATIENT

Conveying or receiving an initial diagnosis of cancer, or the knowledge that cancer has recurred, is among the most difficult of human enterprises, and no amount of either specialized training or forewarning can adequately assuage the intensity of the emotions associated with these encounters. Patients often experience a storm of feelings that may limit useful discussion immediately following the receipt of a diagnosis of cancer. Even the most well-informed patient typically has difficulty processing the complexities of his or her individual situation, including the range of additional diagnostic tests that may be required and the potentially vast array of treatment options and outcomes that lie ahead. And yet, at some point prior to the initiation of treatment, the physician and the patient must discuss the diagnosis, its implications, and therapeutic alternatives. Because of the wide range of potential prognoses (from curable disseminated testicular cancer to the limited lifespan of patients with locally advanced gastric or pancreatic cancer), it is often useful for family members or close friends to be present in the consulting room when detailed discussions of the complexities of either disease or therapy are conducted, both to provide emotional support and to be another "set of ears" during the visit. It is helpful to ask patients directly: "What do you understand about your diagnosis and treatment?" Family members or close associates of the patient may also be especially helpful in developing a written or digital record of the questions posed to and answered by health care providers; many patients find such a record to be especially helpful for later reference.

If the physician is not familiar with the latest treatment options, prompt referral to a specialist, whether a surgical oncologist, radiation oncologist, or medical oncologist, is imperative. The generalist should not be a therapeutic nihilist unless she or he is intimately involved in the field and is well versed in the potential risks and benefits of currently available therapies and clinical trials.

DIAGNOSIS

Diagnostic possibilities are protean for the wide range of human malignancies that may be discovered either in the presence of nonspecific but foreboding symptoms or signs (severe weight loss [see Fig. 118-4], hematuria [see Fig. 100-3], jaundice [see Fig. 133-1]) or in asymptomatic individuals (e.g., during a routine physical examination).[1] The importance of the medical history and physical examination, however, must be emphasized *whether or not* a pathologic diagnosis of cancer has already been confirmed. One of the most important considerations that underlies the approach to both the diagnostic evaluation and choice of cancer treatment (surgical, radiation, and/or systemic therapy) is the patient's basic physiologic condition or "performance status" (Table 164-1). For example, a past medical history of prolonged tobacco smoking (Chapter 363) is not only relevant to a possible diagnosis of lung cancer but also to the ability of a patient to tolerate potentially curable multimodality treatment. Underlying evidence of excessive alcohol consumption (Chapter 364) may play a role in both the tolerance for and metabolism of systemic chemotherapeutic agents. Family histories of cancer can provide prognostic indicators as well as suggest molecularly guided treatment approaches in, for example, women with possible *BRCA1*-related breast or ovarian cancer. It is also critical to assess the environment of care, including the patient's support systems, which may be sorely tested by the experience of a cancer diagnosis and the interventions that ensue. Finally, the physical examination will define the extent of certain sites of measurable malignancy—for example, palpable lymph nodes or enlargement of the spleen or liver—as well as the patient's muscle strength, the presence of possible malignant effusions, and potential central or peripheral neuropathies reflective of metastatic disease or paraneoplastic syndromes. Most importantly, however, the evaluation provides the treating physician with an initial sense of the patient's well-being, or lack thereof, prior to the initiation of therapy.

TABLE 164-1 KARNOFSKY AND ZUBROD PERFORMANCE SCALES

KARNOFSKY PERFORMANCE STATUS SCALE

VALUE	LEVEL OF FUNCTIONAL CAPACITY
100	Normal, no complaints, no evidence of disease
90	Able to carry on normal activity, minor signs or symptoms of disease
80	Normal activity with effort, some signs or symptoms of disease
70	Cares for self, unable to carry on normal activity or to do active work
60	Requires occasional assistance but is able to care for most needs
50	Requires considerable assistance and frequent medical care
40	Disabled, requires special care and assistance
30	Severely disabled; hospitalization is indicated, although death is not imminent
20	Hospitalization is necessary; very sick, active supportive treatment necessary
10	Moribund; fatal processes progressing rapidly
0	Dead

EASTERN COOPERATIVE ONCOLOGY GROUP (ZUBROD) PERFORMANCE SCALE

PERFORMANCE STATUS	DEFINITION
0	Asymptomatic
1	Symptomatic; fully ambulatory
2	Symptomatic; in bed <50% of day
3	Symptomatic; in bed >50% of day
4	Bedridden

Diagnostic Procedures

After a lesion has been found, either on physical examination or following radiographic studies prompted by abnormal laboratory results, a percutaneous biopsy is often indicated for pathologic evaluation. The biopsy must be representative of the entire tumor and be robust enough in size that appropriate investigations (e.g., special immunohistologic stains, flow cytometry, cytogenetics, hormone assays, molecular testing) can be performed before treatment is initiated. If questions remain as to whether the lesion is benign or malignant or about its proper classification, consideration should be given to additional biopsies, and consultation with a reference pathologist may be indicated.

Molecular testing is increasingly useful for the early diagnosis of asymptomatic malignancy.[2] For example, a small number of cases of occult cancer may be subsequently diagnosed among pregnant women whose noninvasive prenatal testing results show discordance with the fetal karyotype.[3] Similarly, analysis of blood for circulating tumor cells (termed a liquid biopsy) can screen for some early cancers or a recurrence of tumor after treatment.

The wide range of molecularly targeted and immunotherapeutic agents active in solid tumors (see Table 164-2 for an abbreviated list of commonly used medications in cancer and https://www.cancer.gov/about-cancer/treatment/drugs/cancer-type for a full listing of all drugs approved by the U.S. Food and Drug Administration) has focused attention on obtaining sufficient tissue so that essential molecular studies (DNA sequencing, RNA expression analyses, FIH [fluorescence in situ hybridization], and immunologic profiling) are performed to guide choices among treatments. Although tumors removed by surgical resection are routinely of sufficient size to permit the full range of diagnostic examinations, active involvement of a skilled interventional radiologist or endoscopist is often required to produce both the size and number of tumor biopsies required for modern cancer therapeutic decision making. Emergent treatment is rarely required before appropriate pretreatment evaluations can be performed. For some tumor sites such as the colon (Chapter 179), one predominant histology is seen, but critical molecular features of the tumor (presence or absence of a mutant *Ras* oncogene) can define therapy. For other tumors, such as in the lung (Chapter 177), the distinction between

ABSTRACT

The care of the patient with cancer requires a broad knowledge of specific histologic diagnoses, an increasing appreciation of the biology and genetics of malignancy, an understanding of cancer immunology, and a broad appreciation of the pharmacology of the systemic agents, both cytotoxic and molecularly targeted, used to treat cancers in addition to standard surgical and radiotherapeutic approaches. The approach to the patient with cancer also requires a commitment to the critical psychosocial aspects of care that are essential for the optimal treatment of the multifaceted medical problems confronted by all cancer patients.

medical oncology
cancer therapy
immunotherapy
targeted therapy
systemic treatment

TABLE 164-2 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER*

DRUG NAME	DRUG CLASS AND/OR MECHANISM	PHARMACOKINETICS/METABOLISM	TOXICITY	INDICATIONS†
Abiraterone acetate (Zytiga)	Inhibits androgen biosynthesis	Do not take with food; inhibits CYP2D6	Joint swelling or discomfort; edema; monitor liver enzymes	Metastatic prostate cancer
Acalabrutinib (Calquence)	Bruton kinase inhibitor	Avoid with proton pump inhibitors, strong CYP3A inhibitors or inducers, and patients with severe hepatic impairment	Opportunistic infection, cytopenias, atrial tachyarrhythmias, headache, diarrhea, musculoskeletal pain	CLL, small lymphocytic lymphoma, mantle cell lymphoma
Afatinib (Gilotrif)	Selective covalent inhibitor of EGFR, HER2, and HER4; inhibits wild-type and selected EGFR mutants	Interacts with P-gp inhibitors which may require dose reduction; dose reduction for moderate renal dysfunction	Acneiform eruption; hypokalemia; diarrhea, stomatitis, and nausea; altered liver function studies; decreased creatinine clearance	NSCLC first line with *EGFR* exon 19 deletions or exon 21 (L858R) mutation as detected by appropriate diagnostic test
Alectinib (Alecensa)	Tyrosine kinase inhibitor inhibiting *ALK* gene abnormalities and *RET* mutations; can inhibit certain *ALK* mutations that follow treatment with crizotinib	Hepatic metabolism by CYP3A4; excreted in the feces	Bradycardia; CK elevations; interstitial pneumonitis	ALK-positive metastatic NSCLC progressive on crizotinib
Amivantamab-vmjw (Rybrevant)	Human *EGFR* and *MET* bispecific antibody targeting *EGFR* exon 20 insertion mutations	Disrupts *EGFR* and *MET* signaling by blocking ligand binding and degrading *EGFR* and *MET*; terminal half-life of about 11 days	Rash; infusion reactions; paronychia; stomatitis; pruritus	NSCLC with *EGFR* exon 20 insertion mutations in patients who have progressed on platinum-based chemotherapy
Anastrozole (Arimidex)	Nonsteroidal aromatase inhibitor; blocks estrogen production selectively	Well absorbed from GI tract, maximum plasma levels within 2 hr; half-life is 50 hr; extensively metabolized in liver; despite hepatic and renal clearance being important, no adjustments needed for abnormal function of these organs because of the wide therapeutic index of this drug	Very well tolerated; asthenia, headache, and hot flashes occur in less than 15% of women; diarrhea, abdominal pain, anorexia, nausea, and vomiting occur in 10% or less; thrombophlebitis has been reported	As adjuvant therapy of breast cancer and for treatment of postmenopausal women with breast carcinoma who have progressed while being treated with tamoxifen
Apalutamide (Erleada)	Androgen receptor inhibitor	If no prior orchiectomy, prescribe a gonadotropin-releasing hormone analog concurrently	Ischemic cardiovascular events, fractures, fatigue, arthralgia, rash, decreased appetite, falls, weight decreased, hypertension, hot flush, diarrhea	Metastatic castration-sensitive prostate cancer or nonmetastatic castration-resistant prostate cancer
Arsenic trioxide (Trisenox)	Novel arsenical differentiating agent	Half-life of this compound is unknown; it is methylated in the liver and eliminated in the urine	The "differentiation syndrome" is dose limiting and includes leukocytosis, fever, dyspnea, chest pain, tachycardia, hypoxia, and sometimes death; corticosteroids seem to benefit this syndrome; QT prolongation is common; common adverse effects include rash, pruritus, headache, arthralgias, anxiety, bleeding, nausea, and vomiting; liver and renal toxicity are uncommon	Relapsed acute promyelocytic leukemia
L-Asparaginase (Elspar), colaspase	Naturally occurring enzyme derived from *Escherichia coli* or *Erwinia carotovora* that cleaves asparagine, an essential amino acid required by rapidly proliferating cells	After IV or IM injection, the drug is metabolized intravascularly by proteolysis; elimination half-life of 8-30 hr	Hypersensitivity can be life-threatening, requiring anaphylaxis precautions and a 2-unit test dose; coagulopathy is common and requires monitoring; nausea, vomiting, abdominal cramps, anorexia, elevated liver function tests, and transient renal insufficiency are common; lethargy, somnolence, fatigue, depression, and confusion are seen, as are pancreatitis and fever	ALL; also used in AML, late-stage CML, CLL, and non-Hodgkin lymphomas
Atezolizumab (Tecentriq)	Humanized monoclonal antibody that binds the programmed death ligand 1 (PD-L1) downregulating anti–T-cell function	No dosage adjustment for mild renal or hepatic insufficiency	Rash; endocrinopathies; immune hepatitis, pancreatitis, pneumonitis, colitis, adrenal insufficiency, diabetes; peripheral edema; fatigue; fever	NSCLC; small cell lung cancer; advanced urothelial cancer patients ineligible for or who have progressed after platinum-containing therapy; hepatocellular cancer; melanoma
Avelumab (Bavencio)	Programmed death ligand-1 (PD-L1) blocking antibody	Can cause fetal harm	Immune-mediated pneumonitis, hepatitis, colitis, endocrinopathies, nephritis; fatigue; musculoskeletal pain; rash; diarrhea	Adult and pediatric patients (12 yr of age and older) with metastatic Merkel cell carcinoma; renal cell carcinoma; urothelial carcinoma
Axitinib (Inlyta)	Avoid strong CYP3A inhibitors or reduce dose	Decrease dose 50% for CYP3A inhibitors, renal, hepatic impairment	Diarrhea, hypertension, fatigue, nausea	Advanced renal cell carcinoma after one treatment failure

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

TABLE 164-2 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER*—cont'd

DRUG NAME	DRUG CLASS AND/OR MECHANISM	PHARMACOKINETICS/METABOLISM	TOXICITY	INDICATIONS†
Azacytidine (Vidaza)	Antimetabolite; induces hypomethylation of DNA, either inducing apoptosis or restoring normal function; at higher doses, acts as a cytidine analog	Not orally bioavailable; metabolized by the liver and excreted in urine; elimination half-life of 4 hr	Myelosuppression is dose limiting; leukopenia, thrombocytopenia, and transient elevation of liver function tests are common; nausea and vomiting and abdominal pain are common	Myelodysplastic syndromes
Bacillus Calmette-Guérin (TICE BCG, TheraCys), BCG	Immunostimulant/vaccine; induces a cellular immune response at the site of instillation	BCG is a live, attenuated bacteria culture; it does not enter the body in viable form; it has no detectable pharmacokinetic fate; in rare cases, a clinical infection can result from treatment, indicating invasion of the body at site of administration into systemic circulation	Urinary symptoms predominate, including dysuria, hematuria, hesitancy, urgency, frequency, and secondary infection; other toxicities include fever, chills, malaise, myalgias/arthralgias, anorexia, nausea, vomiting, and anemia; clinical mycobacterial infection is rare and generally seen only in immunocompromised patients	Intravesical instillation for noninvasive bladder cancer after removal of papillary tumors; also used for some experimental vaccine programs as an adjuvant to the vaccine
Belinostat (Beleodaq)	Histone deacetylase inhibitor; results in accumulation of acetyl groups on histone and nonhistone proteins causing cell cycle arrest and apoptosis	Hepatic metabolism via *UGT1A1* and CYP2A6; excreted in urine	Myelosuppression; peripheral edema and prolonged QT interval; rash; nausea and vomiting; fatigue	Relapsed peripheral T-cell lymphoma
Bendamustine (Treanda)	Alkylating agent	Reduce dose for hematologic toxicity	Nausea, pyrexia, vomiting, hematologic abnormalities	CLL and B-cell non-Hodgkin lymphoma
Bevacizumab (Avastin)	Recombinant humanized monoclonal antibody that binds to all forms of VEGF, preventing binding to its receptors	Administered by IV infusion; half-life is 20 days; the fate of parent drug and metabolites is unknown	Asthenia, pain, nausea/vomiting, diarrhea, anorexia, stomatitis, dermatitis, hypertension, proteinuria; infusion-related reactions rare; hemoptysis, hemorrhage, delayed wound healing, GI perforations; increased risk of thromboembolic events can be severe or fatal	Metastatic colorectal cancer and NSCLC; renal cell carcinoma
Bicalutamide (Casodex)	Nonsteroidal antiandrogen	Well absorbed orally; highly protein bound; converted to inactive metabolites in liver via oxidation and glucuronidation; half-life of several days	Constitutional symptoms predominate, including hot flashes, decreased libido, depression, weight gain, edema, gynecomastia, early disease-site pain (flare reaction), and constipation; nausea, vomiting, anorexia, diarrhea, and dizziness are uncommon; dyspnea, anemia, fever, and rashes are rare	Stage D2 prostate cancer, in combination with an LHRH agonist agent
Binimetinib (Mektovi)	Mitogen-activated protein kinase 1 and 2 inhibitor	Reduce dose if moderate or severe hepatic impairment	Cardiomyopathy, retinopathy, interstitial lung disease, hepatotoxicity, rhabdomyolysis	Unresectable or metastatic melanoma with a *BRAF* V600E or V600K mutation
Bortezomib (Velcade)	Proteasome inhibitor	Metabolized in the liver by CYP2C19 and 3A4; dose reduction for hepatic dysfunction	Cardiovascular; peripheral neuropathy; skin rash; nausea and diarrhea	Multiple myeloma; mantle cell lymphoma
Brentuximab vedotin (Adcetris)	CD30-directed antibody conjugate	Monitor patients taking CYP3A inducers or inhibitors	Progressive multifocal leukoencephalopathy; peripheral neuropathy; neutropenia	Hodgkin lymphoma and anaplastic large cell lymphoma
Brigatinib (Alunbrig)	Multikinase inhibitor	Interacts with strong CYP3A inhibitors; requires dose reduction; avoid grapefruit juice	Hypertension; skin rash; fatigue; increased liver function tests	ALK-positive NSCLC for patients who have progressed on crizotinib
Capecitabine (Xeloda)	Oral antimetabolite prodrug	Readily absorbed by the GI tract, metabolized in vivo to fluorouracil in the liver by carboxylesterase and cytidine deaminase, and then in turn in the peripheral tissues and tumor tissue by thymidine phosphorylase	Myelosuppression and palmar-plantar erythrodysesthesia are dose limiting; diarrhea, fatigue, stomatitis, and hyperbilirubinemia are uncommon; nausea, vomiting, and rash are rare	Metastatic breast cancer and metastatic colorectal cancer; used also in head and neck squamous cell cancer
Cabazitaxel (Jevtana)	Microtubule inhibitor	Caution for patients taking strong CYP3A inducers or inhibitors	Neutropenia and hypersensitivity	Metastatic hormone refractory prostate cancer when docetaxel fails
Cabozantinib	Inhibits many receptor tyrosine kinases; anti-angiogenic	55-hour half-life; take without food	Perforations, fistulas, and hemorrhage	Metastatic medullary thyroid cancer; advanced renal cell carcinoma; advanced hepatocellular cancer

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

Carboplatin (Paraplatin), Carbo, CBDCA	Atypical alkylator; produces intrastrand and interstrand cross-links in DNA via association bonds with the platinum molecule, leading to DNA strand breakage during replication	Rapidly cleared from the blood stream after IV infusion, with a terminal half-life of 2.5 hr; it is cleared largely as unchanged drug by the kidneys	Hemorrhage; thrombocytopenia	Ovarian cancer and used extensively in testicular cancer, squamous cell cancers of the head and neck and cervix, and lung cancer
Carfilzomib (Kyprolis)	Proteasome inhibitor	Drug-drug interactions unlikely; no adjustment for renal impairment; no experience with hepatic impairment	Fatigue, anemia, nausea, thrombocytopenia, dyspnea, diarrhea, and pyrexia; monitor for cardiac, pulmonary, tumor lysis, infusion reactions, thrombocytopenia	Multiple myeloma
Ceritinib (Zykadia)	Inhibitor of ALK tyrosine kinase as well as *ROS1*; also inhibits IGF-1R and the insulin receptor	Metabolized by CYP3A in the liver; dose reduction if concomitant strong CYP3A inhibitors are administered	Bradycardia; QTc prolongation; nausea, vomiting; hyperglycemia; interstitial pneumonitis	NSCLC that is *ALK* positive by an appropriate diagnostic test; demonstrated activity in crizotinib-resistant NSCLC xenograft models
Cetuximab (Erbitux)	Recombinant humanized monoclonal antibody, targeting *EGFR*; competitively inhibits growth factor binding; inhibits autophosphorylation and cell signaling	Metabolism poorly understood; half-life 5-7 days with minimal clearance by kidneys or liver	Infusion reaction, characterized by rapid-onset dyspnea, fever, chills, urticaria, flushing, angioedema, and hypotension, is seen in 40-50% of patients; acneiform rash is common; constitutional symptoms; hypomagnesemia; interstitial lung disease is rare	Metastatic colorectal cancer, head and neck cancer in combination with radiation
Cisplatin (Platinol)—cDDP, DDP, cisplatinum, cis-diamminedichloro-platinum (II)	Atypical alkylator; produces intrastrand and interstrand cross-links in DNA via association bonds with the platinum molecule, leading to DNA strand breakage during replication	After IV infusion, rapid distribution to tissues takes place, and the drug is over 90% protein bound	Nephrotoxicity is dose limiting for an individual dose, and neurotoxicity, especially painful peripheral neuropathy, is dose limiting for cumulative doses; myelosuppression is mild; nausea and vomiting are common but manageable, and anorexia and diarrhea are common; cumulative ototoxicity is also common; chronic renal magnesium and potassium wasting is common and sometimes not reversible; elevated liver transaminases can be seen, whereas alopecia and cardiac conduction abnormalities are rare; adequate renal perfusion and urine output are critical for minimizing renal toxicity; therefore prehydration and adequate posttreatment hydration are used, usually with normal saline solution with or without mannitol, potassium, and magnesium	Used for almost every class of solid tumor and lymphoma; FDA approved for testicular and ovarian cancer and transitional cell carcinoma
Cobimetinib (Cotellic)	Inhibitor of *MEK1* and *MEK2* in the MAPK cascade	Detoxified in the liver by CYP3A4 and UGT2B7; use of strong CYP3A4 inhibitors should be avoided; excreted in feces	Cardiotoxicity; rhabdomyolysis; rash; retinopathy; bleeding	Metastatic or unresectable melanoma for patients with *BRAF* V600E or V600K mutations in combination with vemurafenib
Copanlisib (Aliqopa)	PI-3 kinase inhibitor	Avoid concomitant strong CYP3A inducers and reduce dose of strong CYP3A inhibitors	Hyperglycemia, hypertension, neutropenia, thrombocytopenia, diarrhea, severe cutaneous reactions, nausea, lower respiratory tract infections	Relapsed follicular lymphoma after at least two prior systemic therapies
Crizotinib (Xalkori)	ALK kinase inhibitor; also inhibits *cMET*	Avoid strong CYP3A inhibitors, inducers, or substrates	Hepatotoxicity; pneumonitis; QT interval prolonged	*ALK*-positive NSCLC
Cyclophosphamide	Alkylating agent	Metabolized to its active alkylating species by mixed function oxidases in hepatic microsomes including CYP2A6 and 3A4; decreased activation to therapeutic species in the face of severe hepatic dysfunction	Myelosuppression; immunosuppression; hemorrhagic cystitis; myocarditis; pneumonitis; secondary malignancies; infertility; hyponatremia; veno-occlusive disease; nausea and vomiting; mucositis	Hodgkin and non-Hodgkin lymphoma; leukemias; ovarian cancer; breast cancer; retinoblastoma; neuroblastoma
Cytarabine	Antimetabolite that inhibits DNA polymerase after activation to its nucleotide triphosphate, is incorporated into DNA and RNA and blocks cell cycle progression from G1 to S phase	Metabolized in the liver and excreted by the kidney	Myelosuppression; immunosuppression; CNS, cardiac, and pulmonary toxicity; infection; fever, bone and chest pain and rash within hours of administration (Ara-C syndrome); nausea, diarrhea; mucositis; hepatic dysfunction	AML in adults and children

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

TABLE 164-2 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER*—cont'd

DRUG NAME	DRUG CLASS AND/OR MECHANISM	PHARMACOKINETICS/METABOLISM	TOXICITY	INDICATIONS†
Dabrafenib (Tafinlar)	BRAF kinase inhibitor; selectively inhibits BRAF V600E mutated kinase	Metabolized to active form by CYP isoforms in the liver; absorption delayed by a high-fat meal	Decreased LVEF; skin rash, alopecia, keratoacanthoma and squamous cell carcinoma, palmar-plantar erythrodysesthesia; hyperglycemia; diarrhea; lymphopenia and anemia; abnormal liver function tests	Metastatic or unresectable melanoma with BRAF V600 E mutation or in combination with trametinib if either BRAF V600E or V600K mutations present; NSCLC if BRAF V600E mutation detected by an approved test
Dasatinib (Sprycel)	Multikinase inhibitor including Bcr-Abl and Src	Use with caution in patients with hepatic impairment; CYP3A4 inhibitors: may increase dasatinib drug levels; avoid or monitor closely and consider reducing dose; CYP3A4 inducers: may decrease dasatinib drug levels; avoid or consider increasing dose; antacids: may decrease dasatinib drug levels; avoid simultaneous administration; if needed, administer the antacid at least 2 hr prior to or 2 hr after the dose; H2 antagonists/proton pump inhibitors: may decrease dasatinib drug levels; consider antacids in place of H2 antagonists or proton pump inhibitors	Myelosuppression, bleeding events, fluid retention, diarrhea, headache, musculoskeletal pain, and rash	(Ph+) chronic myeloid leukemia (CML) in chronic phase, or chronic, accelerated, or myeloid or lymphoid blast phase Ph+ CML with resistance or intolerance to prior therapy including imatinib, or Philadelphia chromosome–positive acute lymphoblastic leukemia (Ph+ ALL) with resistance or intolerance to prior therapy
Daunorubicin	Anthracycline antitumor antibiotic; pleiotropic effects including free radical formation, topoisomerase II inhibition; altered mitochondrial function	After IV bolus, widely distributed and metabolized in liver to active and inactive metabolites; half-life of the parent drug is 18 hr, and 25 hr for active metabolite daunorubicinol	Daunorubicin is a vesicant; precautions are necessary; myelosuppression is dose limiting; alopecia, nausea, vomiting, and stomatitis are common; diarrhea, rash, elevated liver function tests, and transient arrhythmias are uncommon; dose-related cardiomyopathy is uncommon below cumulative doses of 400-500 mg/m^2	AML and ALL
Decitabine (Dacogen)	Antimetabolite; inhibits DNA methyltransferase, causing hypomethylation of DNA; this may induce apoptosis or restore normal function to genes that control cellular differentiation and proliferation	Deaminated by cytidine deaminase, found in liver, granulocytes, gut, and blood; elimination half-life is 30 min	Myelosuppression; nausea, vomiting, abdominal pain; constitutional symptoms; elevated liver functions, blood sugar, low serum magnesium, low serum potassium; respiratory toxicity	Myelodysplastic syndromes
Denosumab (Xgeva)	Monoclonal antibody; RANK ligand inhibitor	No drug interaction studies; more hypocalcemia for creatinine clearance <30 mL/min	Use calcium and vitamin D to treat or prevent hypocalcemia; fatigue/asthenia, hypophosphatemia, and nausea; osteonecrosis of jaw	Bone metastases from solid tumors; not in multiple myeloma; giant cell tumor of bone
Dexrazoxane (Zinecard)—ADR-529, ICRF-187	Iron-chelating agent that serves as a free-radical scavenger/cytoprotectant; widespread and rapid	Metabolism is mostly hepatic; half-life is 3-4 hr; parent drug and metabolites are excreted by the kidneys; hepatic impairment not studied; renal impairment suggests 50% dose reduction	Dexrazoxane appears to worsen slightly the leukopenia induced by doxorubicin; mild nausea and vomiting are common; fever, stomatitis, fatigue, anorexia, and hypotension are uncommon; seizure, respiratory arrest, deep venous thrombosis, and significant liver toxicity are rare	Prevent doxorubicin-induced cardiomyopathy
Docetaxel (Taxotere), RP-56976	Docetaxel is a semisynthetic taxane, a class of compounds that inhibit the mitotic spindle apparatus by stabilizing tubulin polymers, leading to death of mitotic cells	After a 1-hr infusion, docetaxel is widely distributed, with elimination half-life of 1 hr and a terminal half-life of 18 hr; extent and by-products of metabolism are not well known; the main excretion route is biliary	Myelosuppression is universal and dose limiting; alopecia is also universal; edema and fluid accumulation, including pleural effusions and ascites, are common and can be dose limiting; fluid accumulation is partially preventable with corticosteroid treatment before and after each cycle of docetaxel; mild sensory or sensorimotor neuropathy is common; mucositis and diarrhea are common and usually mild; hypersensitivity reactions are uncommon and can largely be prevented through premedication with corticosteroids and antihistamines; rash and elevated liver function tests are uncommon	Metastatic breast cancer and first- and second-line NSCLC

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

Doxorubicin (Adriamycin, Rubex), Adria, hydroxydaunorubicin	Anthracycline antitumor antibiotic; pleiotropic effects including free radical formation, topoisomerase II inhibition; altered mitochondrial function	After an IV dose, it is widely distributed in tissues and is 70% protein bound; it is metabolized in the liver to active and inactive forms; it has an elimination half-life of 18 hr or more; most of the drug and metabolites are excreted through the biliary route	Doxorubicin is a potent vesicant, and extravasation precautions are a must; myelosuppression is universal and usually dose limiting with each individual cycle; cardiotoxicity is common and can be dose limiting, although usually subclinical; chronic, cumulative cardiomyopathy is expected when the total dose exceeds 450 mg/m^2; this toxicity can be lessened by the addition of dexrazoxane or by longer infusions; acute cardiac effects, including arrhythmias, are less often seen and are unpredictable; nausea and vomiting are common but manageable; diarrhea and stomatitis are common but usually mild; alopecia, rash, and hyperpigmentation are common	Approved for a variety of cancers and used for many more; most commonly used for breast carcinoma, adult sarcomas, pediatric solid tumors, Hodgkin disease, non-Hodgkin lymphomas, and ovarian cancer
Doxorubicin, liposomal (Doxil)	Novel liposomal preparation of the anthracycline doxorubicin	Doxorubicin metabolized in the liver; significant plasma levels of the principal metabolite, doxorubicinol, not observed with the liposomal preparation, likely because of slow distribution of free doxorubicin to liver; half-life of liposomes in plasma is 55 hr	Myelosuppression is mild but dose limiting; palmar-plantar erythrodysesthesia is common and can occasionally be severe and dose limiting; stomatitis and nausea are common but usually mild; alopecia is uncommon; acute infusion reactions including chest pain, back pain, dyspnea, and wheezing can occur uncommonly	Recurrent metastatic ovarian cancer and AIDS-related Kaposi sarcoma; also used commonly in metastatic breast cancer and multiple myeloma
Durvalumab (Imfinzi)	Human monoclonal antibody that inhibits binding of PD-L1 to PD-1 and CD80, enhancing antitumor effects of T cells	May need to reduce dose or discontinue in the presence of treatment-related nephritis or hepatitis	Hepatotoxicity; renal toxicity; rash; endocrinopathies; colitis and diarrhea; infusion reactions; pneumonitis	Locally advanced or metastatic urothelial carcinoma following progression on platinum-based therapy; extensive stage small cell lung cancer; NSCLC
Enasidenib (IDHIFA)	Inhibitor of the enzyme isocitrate dehydrogenase (IDH2) targeting the R140Q, R172S, and R172K mutant variants of IDH2 to reduce 2-hydroxyglutarate levels and reestablish myeloid differentiation	Hepatic metabolism by way of multiple CYP isoforms and UGTs; primarily excreted in the feces; reduce dose for bilirubin >3 times ULN	Differentiation syndrome (black box warning): fever, respiratory distress, pleural and pericardial effusions, edema, multiorgan dysfunction—must be treated with corticosteroids; electrolyte imbalance; hepatotoxicity; nausea, vomiting, diarrhea; tumor lysis syndrome	AML patients with IDH2 mutations defined by an appropriate diagnostic test
Entrectinib (Rozlytrek)	Tropomyosin receptor kinase inhibitor	Avoid moderate and strong CYP3A inducers, reduce dose with moderate and strong CYP3A inhibitors	Heart failure, CNS side effects, skeletal fractures, hepatotoxicity, hyperuricemia, QT interval prolongation, vision disorders	Metastatic *ROS1*-positive NSCLC
Enzalutamide (Xtandi)	Androgen receptor signaling inhibitor	Take with or without food; 2C8 substrate; no other pathways need adjustments	Fatigue, musculoskeletal pain, dizziness, weakness	Metastatic castrate-resistant prostate carcinoma
Epirubicin (Ellence)	Anthracycline; pleiotropic effects including free radical formation, topoisomerase II inhibition; altered mitochondrial function	Metabolized primarily by liver; parent drug and metabolites glucuronidated and excreted in bile much more than via renal clearance; reduce doses for mild to moderate hepatic dysfunction; severe hepatic dysfunction is contraindicated; half-life is 30-35 hr	Myelosuppression is universal and dose limiting; alopecia is expected; this drug is a vesicant, and precautions must be taken to avoid extravasation into soft tissue around veins; nausea and vomiting are common but usually manageable; stomatitis is common; fatigue is common; detectable cardiac dysfunction at somewhat higher cumulative doses than doxorubicin; secondary leukemia is rare	Adjuvant therapy after optimal surgical treatment of localized breast cancer with involved axillary lymph nodes
Erdafitinib (Balversa)	FGFR kinase inhibitor	Avoid moderate CYP2C9 or strong CYP3A4 inhibitors, moderate or strong CYP2C9 or CYP3A4 inducers, CYP3A4 substrates, OCT2 substrates	Central serous retinopathy retinal pigment epithelial detachment, hyperphosphatemia, stomatitis, fatigue, increased creatinine level, diarrhea, dry mouth, palmar-plantar erythrodysesthesia syndrome	Locally advanced or metastatic urothelial carcinoma with FGFR3 or FGFR2 genetic alterations progressing despite chemotherapy
Eribulin mesylate (Halaven)	Microtubule inhibitor	Reduce dose in patients with hepatic impairment and moderate renal impairment	Neutropenia, peripheral neuropathy, monitor for QT prolongations, nausea, fatigue	Persons with metastatic breast cancer who have previously received at least two chemotherapeutic regimens for the treatment of metastatic disease; prior therapy should have included an anthracycline and a taxane in either the adjuvant or metastatic setting

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

TABLE 164-2 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER*—cont'd

DRUG NAME	DRUG CLASS AND/OR MECHANISM	PHARMACOKINETICS/METABOLISM	TOXICITY	INDICATIONS†
Erlotinib (Tarceva)	Targeted agent	Inhibits the tyrosine kinase domain of the EGFR, leading to inhibition of EGFR autophosphorylation and signaling	Acneiform rash; diarrhea; interstitial lung disease	Second- or third-line therapy of NSCLC; pancreatic cancer, in combination with gemcitabine
Erythropoietin (Epogen, Procrit), EPO, epoetin alpha	Hematopoietic growth factor; stimulates erythrocytic precursors	Detectable in plasma for 24 hr after dosing; distributed to volume approximating total blood volume; degraded by proteolysis within blood compartment; half-life is 4-27 hr; onset of therapeutic effect takes at least 7 days; excretion of intact peptide is negligible	Hypertension is common but usually mild and not dose limiting; injection site pain is common but mild; flulike syndrome and diaphoresis are uncommon; nausea and vomiting are rare; seizures have been reported in patients undergoing dialysis who receive the drug; iron deficiency anemia can occur after prolonged therapy, and concomitant iron dosing may increase effectiveness of erythropoietin; hematocrit values should be monitored closely during therapy to prevent polycythemia and hyperviscosity	The oncology indication is chemotherapy-induced anemia that is symptomatic; also used for anemia of chronic renal failure and HIV-associated anemia
Etoposide (Vespid), VP-16, epipodophyllotoxin; also available as etoposide phosphate (Etopophos)	Plant alkaloid; topoisomerase II inhibitor; partially cell cycle dependent	Etoposide phosphate is rapidly converted to etoposide after IV infusion; etoposide itself is extensively protein bound, is metabolized in liver, and has a half-life of about 10 hr; 50% of oral etoposide is absorbed via GI tract, requiring oral doses to be twice as high as parenteral doses; excreted both unchanged in urine and as metabolites in bile	Myelosuppression, primarily leukopenia, is universal and dose limiting; nausea and vomiting are common with PO administration but rare when the drug is given by IV; stomatitis and diarrhea are rare with normal doses but common with high doses; alopecia is mild or absent; hepatic toxicity and neurologic effects (peripheral neuropathy and CNS changes) are rare; hypotension can occur with rapid administration of etoposide but does not occur commonly when etoposide phosphate is infused over 5 min; secondary AML has been reported after etoposide	Germ cell tumors and SCLC; also used for lymphomas, AML, brain tumors, non-SCLC, and as high-dose therapy in the transplant setting for breast cancer, ovarian cancer, and lymphomas
Everolimus (Afinitor)	m-TOR inhibitor	Hepatic impairment: for advanced HR+ BC, advanced PNET, advanced RCC, or renal angiomyolipoma with TSC patients with hepatic impairment, reduce the starting dose. Strong CYP 3A4 inhibitors: avoid concomitant use. Moderate CYP 3A4 and/or PgP inhibitors: if combination is required, use caution and reduce dose. Strong CYP 3A4 inducers: avoid concomitant use. If combination cannot be avoided, increase dose.	Noninfectious pneumonitis: monitor for clinical symptoms or radiologic changes; fatal cases have occurred. Infections: increased risk of infections, some fatal. Monitor for signs and symptoms, and treat promptly. Oral ulceration: mouth ulcers, stomatitis, and oral mucositis are common. Cases of renal failure (including acute renal failure), some with a fatal outcome, have been observed. Laboratory test alterations: elevations of serum creatinine, blood glucose, and lipids may occur. Decreases in hemoglobin, neutrophils, and platelets may also occur. Monitor renal function, blood glucose, lipids, and hematologic parameters prior to treatment and periodically thereafter. Avoid live vaccines and close contact with those who have received live vaccines. Advanced HR+ BC, advanced PNET, advanced RCC: most common adverse reactions include stomatitis, infections, rash, fatigue, diarrhea, edema, abdominal pain, nausea, fever, asthenia, cough, headache, and decreased appetite. Renal angiomyolipoma with TSC: most common adverse reaction is stomatitis. SEGA with TSC: most common adverse reaction (incidence ≥30%) are stomatitis and respiratory tract infection.	Postmenopausal women with advanced hormone receptor-positive, HER2 negative breast cancer (advanced HR+ BC) in combination with exemestane after failure of treatment with letrozole or anastrozole. Adults with progressive neuroendocrine tumors of creatic origin (PNET) that are unresectable, locally advanced, or metastatic. Adults with advanced RCC after failure of treatment with sunitinib or sorafenib. Adults with renal angiomyolipoma and TSC not requiring immediate surgery. Pediatric and adult patients with TSC who have SEGA that requires therapeutic intervention but cannot be curatively resected.
Exemestane (Aromasin)	Hormonal agent, steroidal aromatase inhibitor	40% of oral exemestane is absorbed from GI tract and increased by a fatty meal; it is highly protein bound in plasma; exemestane is metabolized in liver by cytochrome P450 3A4 and aldoketoreductases	Although generally well tolerated, exemestane is expected to cause or exacerbate hot flashes or intermittent flushing in some women; fatigue and mild nausea are common; vomiting, headache, and dyspnea are uncommon; it is teratogenic and should not be used in premenopausal women	Estrogen-responsive metastatic breast cancer in postmenopausal women whose disease has progressed while undergoing prior hormonal therapy

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

Filgrastim (Neupogen), G-CSF	Hematopoietic growth factor, relatively specific for the granulocyte lineage	After a bolus SQ injection, peak plasma levels of filgrastim occur in 2-6 hr, whereas the elimination half-life is generally 7 hr or less; metabolism is via proteolysis in the blood compartment; the intact molecule is largely absent from bile or urine	Mild bone pain is common; low-grade fever, myalgias, arthralgias, and transient hypotension are uncommon, as are hyperuricemia and elevations of lactate dehydrogenase and alkaline phosphatase; leukocytosis leading to hypoxia or capillary leak syndrome has been reported; anaphylaxis or allergic reaction is rare	Approved for minimization of granulocytopenia after myelosuppressive chemotherapy; also used to speed recovery of granulocytes in the setting of neutropenic fever after chemotherapy, for myelodysplastic syndromes, for congenital agranulocytosis, for cyclic neutropenia, and for mobilization of peripheral blood stem cells from patients or donors for transplant
Fludarabine (Fludara), FAMP	Purine nucleotide analog antimetabolite; only partially cell cycle–dependent	Fludarabine is available only by the parenteral route; after IV administration, the drug is metabolized to 2-fluoroara-A and widely distributed in tissues; it has an elimination half-life of 9-10 hr; the drug and metabolite are excreted primarily by the kidneys	Neurotoxicity, including cortical blindness, confusion, somnolence, coma, and demyelinating lesions, is dose limiting, but the lower doses that are conventionally used rarely produce these adverse effects; at these doses, mild myelosuppression is the most common toxicity, with cumulative lymphopenia being the most clinically important; nausea, vomiting, and other GI toxicities are rare; alopecia and rash are also rare	Approved for the treatment of CLL; also used for low-grade lymphomas and for AML
5-Fluorouracil (Adrucil, Efudex), 5-FU	Pyrimidine antimetabolite; inhibitor of thymidylate synthase; partially cell cycle dependent	80% of IV drug is metabolized to inactive dihydro-5-FU by dihydropyrimidine dehydrogenase in the liver; the rest of the drug is activated to fluorodeoxyuridine monophosphate in target cells; elimination half-life is 20 min; excretion is via the kidneys	GI toxicities, primarily mucositis for bolus injections and diarrhea for prolonged infusions, are dose limiting; rare patients with dihydropyrimidine dehydrogenase deficiency have excessive GI toxicity; myelosuppression is generally less with continuous infusion schedules; nausea and vomiting are uncommon and mild; dermatitis and other cutaneous toxicities, including hand-foot syndrome, are common; cerebellar ataxia and myocardial ischemia are rare	Approved for colon, rectum, gastric, pancreas, and breast carcinomas and used for a wide range of other neoplasms in combination regimens; used for intrahepatic arterial infusion for liver metastases from GI tumors; also used topically for various cutaneous neoplasms and disorders
Flutamide (Eulexin)	Nonsteroidal antiandrogen	Good oral bioavailability, with peak plasma levels after an oral dose at 1-2 hr; metabolized to active and inactive forms in the liver; half-life is 8-10 hr	Generally well tolerated; gynecomastia, galactorrhea, and impotence are common; nausea, vomiting, diarrhea, mild myelosuppression, myalgias, and elevated liver function tests are rare	Prostate carcinoma
Fulvestrant (Faslodex) estrogen receptor antagonist	Binds to the ER, leading to degradation and loss of ER from the cell	Peak plasma levels reached in 7 days, half-life is 40 days; metabolized by the liver microsomal P4503A4 systems	Constitutional symptoms, including hot flashes; peripheral edema; nausea, vomiting	ER+ metastatic breast cancer in postmenopausal women
Gemcitabine (Gemzar)	Antimetabolite; gemcitabine is a nucleoside analog that exhibits cell cycle–dependent and S-phase–specific cytotoxicity, likely because of inhibition of DNA synthesis	After IV infusion, the drug is rapidly distributed and has a half-life of less than 2 hr; it is metabolized throughout the body to inactive forms; parent drug and metabolite are excreted principally by the kidneys	Myelosuppression, including anemia, is mild but dose limiting; nausea and vomiting are mild but common; diarrhea and edema are sometimes seen; elevated transaminases are common, as is fever during drug administration; hematuria and proteinuria are uncommon; acute dyspnea and rash are uncommon; paresthesias and CNS depression are rare	Advanced pancreatic adenocarcinoma, NSCLC, and metastatic breast cancer; also extensively used in bladder cancer
Hydroxyurea (Hydrea)—hydroxycarbamide	Antimetabolite; inhibitor of ribonucleotide reductase, which converts nucleotides to the deoxyribose forms for DNA synthesis; cell cycle dependent	The drug is well absorbed; drug levels peak in the blood 2 hr after the dose is administered; half-life is 2-5 hr; metabolism to inactive forms in the liver; renal excretion is the route of elimination	Myelosuppression is common and dose limiting; other toxicities include rash, headache, fever, and hyperuricemia; nausea and vomiting are uncommon; liver toxicity and serious neurologic toxicity are rare	FDA approved for CML; commonly used for other myeloproliferative disorders; also used occasionally for metastatic melanoma, refractory ovarian carcinoma, and squamous cell carcinoma of the cervix and the head and neck
Ibrutinib (Imbruvica)	Irreversible inhibitor of Bruton tyrosine kinase altering B-cell receptor signaling	Hepatic metabolism by CYP3A and CYP2D6; dose reduction for hepatic dysfunction	Myelosuppression; cardiovascular; fatigue; skin rash; hyperuricemia; diarrhea, nausea; dry eyes; musculoskeletal pain	CLL and small lymphocytic lymphoma; mantle cell lymphoma; marginal zone lymphoma; Waldenström macroglobulinemia; chronic GVHD
Idelalisib (Zydelig)	Phosphatidylinositol 3-kinase delta inhibitor; results in apoptosis of malignant B cells	Metabolized in the liver by aldehyde oxidase and CYP3A	Hepatotoxicity; allergic reactions; myelosuppression; diarrhea; cutaneous reactions; infection; pneumonitis	Second-line therapy of CLL in combination with rituximab; follicular B-cell NHL; small lymphocytic lymphoma

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

TABLE 164-2 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER*—cont'd

DRUG NAME	DRUG CLASS AND/OR MECHANISM	PHARMACOKINETICS/METABOLISM	TOXICITY	INDICATIONS†
Ifosfamide (Ifex)	Classic alkylating agent; not cell cycle dependent	After an intravenous dose, ifosfamide is activated by hepatic microsomal enzymes; it is then converted to inactive metabolites in the liver; the active form of the drug is the same as that for cyclophosphamide; the elimination half-life of the drug is 7-15 hr; the metabolites and some unchanged drug are excreted in the urine	Myelosuppression, hemorrhagic cystitis, and CNS toxicity are all fairly common and can be dose limiting; hemorrhagic cystitis can largely be prevented by co-administration of the uroprotective agent mesna, and nausea and vomiting are minimized with modern antiemetic regimens; the CNS toxicity, including lethargy, stupor, coma, myoclonus, and seizures, is usually mild and completely reversible; it is worse with impaired renal function; renal dysfunction, usually reversible, is also seen with ifosfamide; hepatic toxicity, diarrhea, and rash are rare	Approved for the treatment of recurrent germ cell tumors; used for many other tumor types, including adult sarcomas, lymphoma, Hodgkin disease, breast cancer, and ovarian cancer
Imatinib (Gleevec)	Bcr-Abl tyrosine kinase inhibitor; also inhibits platelet-derived growth factor (PDGF), c-Kit, and stem cell factor (SCF)	Rapid oral absorption; metabolized in the liver by CYP3A4; AUC increased by severe hepatic dysfunction; dose reduction for renal dysfunction	Edema, ascites, chest pain; fatigue; skin rash; increased LDH; nausea, diarrhea; muscle cramps; increased serum creatinine and liver function tests	CML; ALL that is Philadelphia chromosome positive; gastrointestinal stromal tumors; myelodysplastic syndrome associated with PDGF receptor gene rearrangements
Infigratinib (Truseltiq)	Receptor tyrosine kinase inhibitor that blocks fibroblast growth factor receptors FGFR1, FGFR2, FGFR3; blocks FGFR signaling from activating receptor mutations and gene fusions	Metabolized by CYP3A4; excreted in feces. Steady-state concentrations increased by 50-100% in patients who have mild to moderate liver dysfunction, so the dose must be reduced. Avoid coadministration of proton pump inhibitor.	Hyperphosphatemia requiring monitoring and dose adjustment	Unresectable or locally advanced/metastatic cholangiocarcinoma with *FGFR2* fusion or other rearrangement
Ipilimumab (Yervoy)	Human CTLA-4–blocking antibody	No formal pharmacokinetic drug interaction studies have been conducted; no clinically important differences in clearance of ipilimumab were found between patients with renal impairment and patients with normal renal function; no clinically important differences in clearance of ipilimumab were found between patients with mild hepatic impairment and normal hepatic function	Immune-mediated adverse reactions; fatigue, diarrhea, pruritus, rash, and colitis	Unresectable or metastatic melanoma; NSCLC; mesothelioma; renal cell cancer; hepatocellular cancer; colorectal cancer (MSI-high)
Irinotecan (Camptosar)—CP T-11	Semisynthetic camptothecin, which functions as a topoisomerase I inhibitor; partly cell cycle dependent	Converted partially from active lactone form to inactive carboxylate form; active metabolite of irinotecan, SN-38, also exists in lactone and inactive carboxylate form in equilibrium in plasma; SN-38 is inactivated by glucuronidation in the liver; SN-38 is responsible for the majority of antitumor activity attributed to parent drug; half-life of irinotecan is 8 hr, whereas half-life of SN-38 is 12 hr	Myelosuppression, primarily neutropenia, is common and dose limiting; diarrhea is also common and can be dose limiting; diarrhea can occur as part of a cholinergic syndrome, along with cramping, nausea, and vomiting, during or immediately after drug administration or for several days after drug administration; anticholinergic and antidiarrheal agents will curtail the immediate diarrhea and other GI symptoms partially but are less effective in treating the delayed diarrhea; flushing, rash, and alopecia are common; significant hepatic, renal, neurologic, or pulmonary toxicities are rare	Irinotecan is FDA approved for refractory or recurrent metastatic colon cancer, and it has now been used in other malignancies, including lung cancer, ovarian cancer, and lymphoma
Ixabepilone (Ixempra)	Microtubule inhibitor	In combination with capecitabine, must not be given to patients with AST or ALT >2.5 × ULN or bilirubin >1 × ULN; dose reduction is recommended when administering ixabepilone as monotherapy to patients with hepatic impairment; no formal renal impairment study; inhibitors of CYP3A4 may increase plasma concentrations of ixabepilone; dose of ixabepilone must be reduced with strong CYP3A4 inhibitors; inducers of CYP3A4 may decrease plasma concentrations of ixabepilone; alternative therapeutic agents with low enzyme induction potential should be considered	Peripheral neuropathy: monitor for symptoms of neuropathy, primarily sensory; neuropathy is cumulative, generally reversible, and should be managed by dose adjustment and delays; myelosuppression: primarily neutropenia; monitor with peripheral blood cell counts and adjust dose as appropriate; hypersensitivity reaction: must premedicate all patients with an H1 antagonist and an H2 antagonist before treatment; fatigue/asthenia, myalgia/arthralgia, alopecia, nausea, vomiting, stomatitis/mucositis, diarrhea, and musculoskeletal pain	Combination with capecitabine is indicated for the treatment of metastatic or locally advanced breast cancer in patients after failure of an anthracycline and a taxane; as monotherapy is indicated for the treatment of metastatic or locally advanced breast cancer in patients after failure of an anthracycline, a taxane, and capecitabine

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

Ixazomib (Ninlaro)	Inhibits 20 S proteasome	Absorption decreased by high-fat meals; hepatic metabolism; reduce dose for CrCl <30 mL/min and for total bilirubin >1.5 ULN	Myelosuppression; skin rash; peripheral neuropathy	Multiple myeloma in combination with lenalidomide and dexamethasone as second-line therapy
Lapatinib (Tykerb)	EGRF and HER2 tyrosine kinase inhibitor	Extensive metabolism spread over several enzymes	Hepatotoxicity; decreased left ventricular ejection fraction; diarrhea; some QT interval prolongation	HER2+ breast cancer, with capecitabine; treatment with anthracycline, taxane, trastuzumab failed
Larotrectinib (Vitrakvi)	Neurotrophic receptor tyrosine kinase inhibitor	Avoid strong CYP3A4 inhibitors, strong CYP3A4 inducers, and sensitive CYP3A4 substrates	Neurotoxicity, hepatotoxicity, nausea, vomiting, dizziness, cough, constipation, diarrhea	Metastatic or unresectable solid tumors with a neurotrophic receptor tyrosine kinase gene fusion
Lenalidomide (Revlimid)	Antiangiogenesis agent, immunomodulator	Mechanism of action not fully characterized; an immunomodulatory agent that inhibits angiogenesis in some cells; inhibits bone marrow secretion of IL-6, VEGF, and TNF-α	Myelosuppression; diarrhea, rash, fatigue; increased risk of DVT and PE	Transfusion-dependent anemia due to low- or intermediate-risk myelodysplasia with 5q deletion; multiple myeloma
Lenvatinib (Lenvima)	Multitargeted tyrosine kinase inhibitor *(VEGFR, FGFR, PDGFR, KIT, RET)*	Metabolized in the liver by CYP3A and aldehyde oxidase; dose reduction for hepatic insufficiency	Hypertension; alters thyroid suppression with TSH elevation and hypothyroidism; gastrointestinal toxicity and bowel fistula formation; hepatotoxicity; skin toxicity; hypocalcemia; renal toxicity	Renal cell carcinoma in combination with everolimus; differentiated thyroid cancer that is radioactive iodine refractory
Letrozole (Femara)	Nonsteroidal aromatase inhibitor	Letrozole has nearly 100% bioavailability, is metabolized in the liver, glucuronidated, and excreted by the kidneys; half-life is 2 days; with daily administration, steady-state plasma levels are reached in 2-6 wk	This drug is generally well tolerated; muscle aches and nausea are uncommon; hot flashes and fatigue are uncommon; weight change, urticaria, and dyspepsia are rare	Metastatic estrogen-responsive breast cancer in postmenopausal patients
Leucovorin calcium (Wellcovorin) citrovorum factor, folinic acid, FA, LV	Tetrahydrofolate derivative and enzyme cofactor for thymidylate synthase and other purine and pyrimidine synthesis steps; bypasses the dihydrofolate reductase step, which is inhibited by methotrexate and therefore can be used to "rescue" normal cells from the toxicity of methotrexate after high doses are administered; in addition, leucovorin potentiates the toxicity of fluoropyrimidines such as fluorouracil by strengthening the association of the drug	Leucovorin has excellent bioavailability by the oral or parenteral route; it is oxidized in cofactor reactions throughout the body and is also partly metabolized; it has an elimination half-life of 2-4 hr; excreted in the urine	Leucovorin is generally very well tolerated; it occasionally causes stomach upset or nausea, rash, diarrhea, and headache; allergic reactions have been reported	Used for rescue of high-dose methotrexate therapy for a variety of neoplasms and as a potentiator of fluoropyrimidines therapy in GI malignancies, particularly colorectal cancer
Leuprolide acetate (Lupron)—leuprorelin acetate	Gonadotropin-releasing hormone agonist, which serves to paradoxically shut down the pituitary release of gonadotropins with chronic exposure; this results in a dramatic decrease in gonadal estrogens and androgens and growth inhibition of hormone-dependent neoplasms	After an SQ injection, about 90% of the drug is eventually absorbed; the depot form of the drug is absorbed slowly over days, whereas the injectable solution is absorbed over several hours; the elimination half-life of the drug once in the serum is 3 hr; metabolism and excretion are not well delineated but are clinically unimportant	Usually well tolerated, but adverse effects can affect many systems, including endocrine (hot flashes, impotence, gynecomastia, breast tenderness, diminished libido, amenorrhea, atrophic vaginitis, increased cholesterol); GI (nausea, constipation, anorexia, diarrhea); hepatic (elevation of transaminases); dermatologic (rash, changes in body hair composition, pruritus); and neuropsychiatric (insomnia, depression, emotional lability, lethargy, memory loss); significant cardiac toxicity is rare	Approved for the treatment of hormone-dependent advanced prostate cancer; also used for breast cancer and endometriosis
Lurbinectedin (Zepzelca)	Alkylating agent	Avoid strong or moderate CYP3A inhibitors and strong or moderate CYP3A inducers	Myelosuppression, hepatotoxicity, increased creatinine level, hyperglycemia, nausea, musculoskeletal pain, constipation, dyspnea, decreased sodium level	Metastatic SCLC progressing despite platinum-based chemotherapy

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

TABLE 164-2 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER*—cont'd

DRUG NAME	DRUG CLASS AND/OR MECHANISM	PHARMACOKINETICS/METABOLISM	TOXICITY	INDICATIONS†
Methotrexate (Mexate, Folex, others)—MTX, amethopterin	Antifolate antimetabolite; interferes with nucleotide synthesis by inhibiting dihydrofolate reductase; cell cycle dependent	Good oral bioavailability at low doses; after oral or IV dosing, it is distributed throughout the body water compartment; it will accumulate in "third-space" fluid compartments and exhibit prolonged toxicity and therefore should be used with caution, if at all, in patients with significant pleural or peritoneal fluid; minimally metabolized in the liver; half-life is 3 hr; even low concentrations of drug after most of the drug is eliminated can contribute to significant toxicity; therefore dosing based on renal function is critical; excretion of this drug is mostly renal	Myelosuppression is expected and is usually dose limiting; stomatitis and diarrhea are common; nausea and vomiting are uncommon; renal toxicity is uncommon and usually reversible but can be severe; many types of skin reactions can occur but are uncommon; pulmonary fibrosis and hepatic fibrosis are rare; encephalopathy is rare with moderate- to low-dose therapy but is more common with high doses, intrathecal administration, or concomitant CNS radiation; it can be severe and permanent	Approved for a wide spectrum of malignant and nonmalignant diseases; most often used for acute leukemias, lymphomas, breast cancer, bladder cancer, squamous cell cancers, and sarcomas
Midostaurin (Rydapt)	Tyrosine kinase inhibitor targeting *FLT3, FLT3 ITD, KIT, PDGFR, VEGFR2,* and *PKC* family	Metabolized by CYP3A4 in the liver	Cardiovascular (edema and QTc prolongation); headache and fatigue; electrolyte abnormalities and hyperglycemia; nausea and vomiting; myelosuppression; abnormal liver function tests; infection	FLT3 mutation-positive AML in combination with cytarabine and daunorubicin; mast cell leukemia; systemic mastocytosis
Neratinib (Nerlynx)	Irreversible inhibitor of EGFR and HER2 kinases	Hepatic metabolism by CYP3A4; dose reduction for severe hepatic dysfunction	Severe diarrhea with dehydration; hepatic toxicity requiring careful monitoring of liver function	Adjuvant therapy of HER2-positive breast cancer following adjuvant trastuzumab-associated therapy
Nilotinib (Tasigna)	Kinase inhibitor including Bcr-Abl	Dose adjustment may be required for hematologic and nonhematologic toxicities and drug interactions; lower starting dose is recommended in patients with impairment (at baseline); do not consume food for at least 2 hr before the dose is taken and for at least 1 hr after	Prolongs QT interval; rash, pruritus, headache, nausea, fatigue, myalgia, nasopharyngitis, constipation, diarrhea, abdominal pain, vomiting, arthralgia, pyrexia, upper respiratory tract infection, back pain, cough, and asthenia; hematologic adverse drug reactions include myelosuppression: thrombocytopenia, neutropenia, and anemia	Newly diagnosed adult patients with Philadelphia chromosome–positive chronic myeloid leukemia (Ph+ CML) in chronic phase; also, the treatment of chronic and accelerated phase Ph+ CML in adult patients resistant to or intolerant to prior therapy that included imatinib
Niraparib (Zejula)	Poly (ADP-ribose) polymerase enzyme inhibitor	Metabolized by carboxylesterases and then glucuronidated	Hypertension; skin rash; fatigue; nausea and constipation; myelosuppression; weakness and back pain; hepatic dysfunction	Ovarian and primary peritoneal cancers in complete or partial response following platinum-containing chemotherapy
Nivolumab (Opdivo)	Human anti-PD-1 monoclonal antibody; releases PD-1 pathway inhibition to improve immune response	Prolonged (>20 day) half-life	Endocrinopathies; colitis; encephalitis; pneumonitis; hypophysitis; rash; if severe may require systemic corticosteroids; infusion reactions	Colorectal cancer with microsatellite instability-high (MSI-H) or mismatch repair deficient (dMMR) that is metastatic and has progressed following fluoropyrimidine, oxaliplatin, and irinotecan; head and neck squamous cell cancer that is recurrent or progressed on platinum-containing chemotherapy; Hodgkin lymphoma; metastatic melanoma; NSCLC; advanced renal cancer; advanced urothelial cancer; esophageal cancer or gastroesophageal junction adenocarcinoma; hepatocellular cancer; mesothelioma; squamous cancer of the head and neck
Obinutuzumab (Gazyva)	Anti-CD20 monoclonal antibody; upon binding to CD20 on B cells, initiates ADCC	No dosage adjustments for renal or hepatic dysfunction	Hypophosphatemia; hypocalcemia; hyperkalemia; blood count suppression; altered liver and kidney function; infection; cough	CLL previously untreated in combination with chlorambucil; follicular lymphoma in combination with bendamustine in patients refractory to rituximab-containing regimens

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

Octreotide, octreotide long-acting (Sandostatin, Sandostatin LA), l-cysteinamide	Synthetic peptide analog of somatostatin; inhibits other GI peptide actions, such as serotonin, insulin, glucagon, and gastrin	Not orally bioavailable but rapidly absorbed after SQ administration; metabolized by hydrolysis throughout the body; no active metabolites; half-life of elimination is about 1.5 hr; intact drug is cleared via the kidneys	GI adverse effects are dose limiting and include abdominal pain, vomiting, loose stool, occasional fat malabsorption, bloating, and cholelithiasis; elevations of liver function tests can also occur, but frank hepatitis is rare; skin reactions, such as pain at the injection site or flushing, rash, or skin thinning, are sometimes seen; constitutional symptoms, including rhinorrhea, xerostomia, sweating, throat discomfort, and vertigo, can be bothersome; hyperglycemia or hypoglycemia can occur; cardiac side effects, including angina, congestive heart failure, and hypotension or hypertension, are uncommon; anxiety, depression, fatigue, and anorexia are uncommon, and seizures are rare	Approved for carcinoid tumors causing carcinoid syndrome and for vasoactive peptide–secreting tumors; also used for refractory diarrhea, either cancer related or treatment related, in patients with cancer
Olaparib (Lynparza)	Inhibitor of poly (ADP-ribose) polymerase enzyme; produces synthetic lethality in BRCA1/2-deficient tumor cells	Hepatic metabolism by CYP3A4; Cmax increased in patients with mild hepatic dysfunction; avoid concomitant use of CYP3A inhibitors	Peripheral edema; fatigue and headache; skin rash; nausea and abdominal pain; anemia and lymphopenia; myalgias; increased serum creatinine	*BRCA*-mutant ovarian cancer previously treated with three or more lines of therapy; maintenance therapy for ovarian cancer in complete or partial remission following platinum-based therapy
Osimertinib (Tagrisso)	Irreversible inhibitor of EGFR tyrosine kinase; binds to mutant forms of EGFR (*T970M, L858R*, exon 19 deletions); less active against wild-type EGFR	Metabolized by CYP3A and excreted in the feces; avoid concomitant use of strong CYP3A4 inducers	Bone marrow suppression; cardiotoxicity, decline in LVEF and prolongation of QTc; skin rash; impaired fertility; diarrhea; keratitis; pneumonitis	Metastatic NSCLC that is *T790M* mutation positive
Oxaliplatin (Eloxatin)	Platinating agent; DNA disrupted via intrastrand and interstrand cross-links with two strong platinum association bonds in the molecule, which induces apoptosis beyond a certain level of DNA damage in malignant cells	After IV administration, rapid distribution into tissues occurs, as well as rapid spontaneous conversion via hydrolysis into active drug and metabolites; the terminal half-life is long (>300 hr) but represents minimal plasma levels of the hydrolyzed drug; elimination of platinum metabolites is via the kidneys	Neurotoxicity, in the form of a transient neuropathy with each dose and a persistent, cumulative typical sensory polyneuropathy, is very common and dose limiting; myelosuppression is expected but mild and only sometimes dose limiting; fatigue and nausea are common but mild; diarrhea, stomatitis, edema, cough, hypersensitivity reactions, and extravasation injury are rare	Approved for metastatic colorectal cancer in combination with 5-FU/leucovorin
Paclitaxel (Taxol, Onxol)	Naturally occurring taxane molecule; inhibits depolymerization of tubulin in the spindle apparatus, thereby inducing apoptosis in dividing cells	After IV administration, the drug exhibits a large volume of distribution and undergoes metabolism in the liver; the elimination half-life is 15-50 hr; excretion of drug and metabolites is predominantly via the bile	Paclitaxel is an irritant or mild vesicant when extravasated into subcutaneous tissue; myelosuppression, predominantly neutropenia, is expected and is dose limiting; shorter infusions of the same dose produce less neutropenia; mucositis is also very common, particularly with longer infusions; peripheral neuropathy is common, usually mild, and increases with cumulative dose; acute neuromyopathy is also common and occurs for several days after each dose; this syndrome may require opiate analgesics to control pain; cardiovascular adverse effects, including hypertension, hypotension, premature contractions, and bradyarrhythmias, are common but rarely require intervention; hypersensitivity reactions to paclitaxel, including urticaria, wheezing, chest pain, dyspnea, and hypotension, are common but are reduced in frequency and severity by premedication with corticosteroids and histamine-1 and histamine-2 antihistamines (the recommended regimen is dexamethasone, 20 mg PO 12 and 6 hr prior to paclitaxel and diphenhydramine, 50 mg, and cimetidine)	Approved for salvage therapy in ovarian cancer and for breast cancer in both the metastatic and adjuvant settings; used also in persons with lung cancer, head and neck cancer, and bladder cancer
Paclitaxel, protein bound (Abraxane)	Taxane; an albumin-bound form of paclitaxel with a mean particle size of approximately 130 nanometers	No change in patients with mild to moderate hepatic dysfunction	Neutropenia, thrombocytopenia, anemia, hypersensitivity reactions, hypotension, cardiovascular events, dyspnea, cough, sensory neuropathy, arthralgias/myalgias, nausea/vomiting, asthenia	Metastatic breast cancer after failure of combination chemotherapy or relapse with 6 mo of adjuvant chemotherapy; also approved for NSCLC

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

TABLE 164-2 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER*—cont'd

DRUG NAME	DRUG CLASS AND/OR MECHANISM	PHARMACOKINETICS/METABOLISM	TOXICITY	INDICATIONS†
Palbociclib (Ibrance)	Reversible small molecule inhibitor of cyclin-dependent kinases 4 and 6 affecting cell cycle progression through the G1/S phase	Metabolized by the liver by CY3A and sulfotransferase; avoid simultaneous use of strong CYP3A inhibitors	Fatigue; alopecia and skin rash; nausea, stomatitis, diarrhea, infection; blood count suppression, infection	Advanced breast cancer that is ER positive, HER2 negative in combination with an aromatase inhibitor as initial therapy for postmenopausal women
Pamidronate (Aredia), APD, aminohydroxypropylidene diphosphonate	Organic bisphosphonate; inhibitor of bone resorption by osteoclasts	After IV administration, the drug concentrates in the bone, spleen, and liver; its metabolism is not well characterized; it has a terminal half-life of about 27 hr; 50% of the parent drug is eliminated in the urine	Pamidronate is usually quite well tolerated; hypotension, syncope, tachycardia, and even atrial fibrillation have been reported uncommonly during the infusion; hypocalcemia, hypophosphatemia, hypokalemia, and hypomagnesemia occur commonly but only rarely require intervention; nausea, vomiting, and somnolence are rare	Approved for malignancy-induced hypercalcemia; may lead to pain relief and even tumor shrinkage of bone metastases in multiple myeloma, breast cancer, and prostate cancer
Panitumumab (Vectibix)	Recombinant, fully humanized IgG2 kappa monoclonal antibody that binds specifically to EGFR, competitively inhibiting ligand binding to the receptor	Steady-state levels are reached by the third infusion; elimination half-life is about 7.5 days	Rash, which may be severe; diarrhea; infusion reactions; hypomagnesemia; pulmonary fibrosis	Previously treated EGFR-expressing metastatic colorectal cancer
Panobinostat (Farydak)	Histone deacetylase inhibitor, affects chromatin remodeling	Hepatic metabolism in part through CYP3A; reduce dose for hepatic dysfunction	ECG abnormalities; fatigue; electrolyte abnormalities; diarrhea; blood count suppression; infection; hyperbilirubinemia	Multiple myeloma in combination with bortezomib and dexamethasone in patients who have received 2 prior regimens
Pazopanib (Votrient)	Inhibits large number of tyrosine kinases	Take without food; reduce dose for mild to moderate hepatic impairment; avoid severe hepatic impairment; interacts with many metabolizing enzymes	Diarrhea, hypertension, nausea, anorexia, vomiting, hair color depigmentation	Renal cell carcinoma; also approved for soft tissue sarcoma
Pembrolizumab (Keytruda)	Human monoclonal antibody against programmed cell death-1 (PD-1) activity that inhibits negative immune regulation to enhance antitumor effects	Long half-life (22 days)	Peripheral edema; rash; fatigue; endocrinopathies; electrolyte abnormalities; hyperglycemia; nausea, diarrhea, colitis; abnormal liver function tests	Squamous cell cancers of the head and neck; Hodgkin lymphoma, melanoma, microsatellite instable (MSI-H) or mismatch repair deficient solid tumors and colorectal cancers that have no alternative treatment options; NSCLC first-line metastatic in patients with high (50%) PD-L1 expression that are EGFR or ALK negative and first-line therapy for metastatic nonsquamous NSCLC in combination with pemetrexed and carboplatin; urothelial carcinoma that has progressed on platinum-containing therapy; triple-negative breast cancer; cervical cancer; cutaneous squamous cell cancer; endometrial cancer that is MSI-high; esophageal, gastric, and gastroesophageal junction adenocarcinoma; hepatocellular cancer; Merkel cell carcinoma; renal cell cancer; primary large B-cell lymphoma
Pemetrexed (Alimta)	Antimetabolite; inhibits folate-dependent enzymes thymidylate synthetase, dihydrofolate reductase, and glycinamide ribonucleotide formyltransferase, which are involved in the de novo synthesis of thymidine and purine nucleotides, leading to inhibition of DNA and RNA synthesis and function; metabolized intracellularly to its highly active polyglutamated form	Excreted in urine with 90% of drug unchanged	Myelosuppression; nausea, vomiting, diarrhea; rash; dyspnea and fatigue	Mesothelioma and NSCLC

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

Pertuzumab (Perjeta)	HER2/neu receptor antagonist antibody; HER2 testing: perform using FDA-approved tests by laboratories with demonstrated proficiency	Of 402 patients who received Perjeta in the randomized trial, 60 patients (15%) were 65 yr of age and 5 patients (1%) were 75 yr of age; no overall differences in efficacy and safety of Perjeta were observed between these patients and younger patients; based on a population pharmacokinetic analysis, no significant difference was observed in the pharmacokinetics of pertuzumab between patients <65 yr (n = 306) and patients ≥65 yr (n = 175)	Left ventricular dysfunction: monitor LVEF and withhold dosing as appropriate; reactions, hypersensitivity reactions/anaphylaxis: monitor for signs and symptoms; if a significant infusion-associated reaction occurs, slow or interrupt the infusion and administer appropriate medical therapies; in combination with trastuzumab and docetaxel: diarrhea, alopecia, neutropenia, nausea, fatigue, rash, and peripheral neuropathy	First-line HER2+ metastatic breast cancer
Pomalidomide (Pomalyst)	Immunomodulator, analog of thalidomide, decreases proliferation of myeloma cells, enhances T-cell–mediated immunity, and has antiangiogenic properties	Metabolized by CYP3A4 and CYP1A2; systemic exposure increased by hepatic dysfunction; avoid use with concomitant CYP1A2 inhibitors; reduce dose for renal or hepatic dysfunction	Thromboembolism; hematologic toxicity; hepatotoxicity; hypersensitivity; neurotoxicity; confusion; tumor lysis syndrome; fatigue; nausea; diarrhea; infection	Multiple myeloma in combination with dexamethasone as third-line therapy
Ponatinib (Iclusig)	Kinase inhibitor	For strong CYP3A inhibitors: reduce dose if co-administration cannot be avoided; renal or hepatic impairment not studied	Arterial thrombosis and hepatotoxicity have boxed warnings; nonhematologic adverse reactions (≥20%) were hypertension, rash, abdominal pain, fatigue, headache, dry skin, constipation, arthralgia, nausea, and pyrexia; hematologic adverse reactions included thrombocytopenia, anemia, neutropenia, lymphopenia, and leukopenia	CML and Philadelphia chromosome–positive acute ALL
Ramucirumab (Cyramza)	Monoclonal antibody targeting the vascular growth factor receptor 2, inhibiting endothelial cell proliferation and angiogenesis	Half-life 14 days	Infusion reaction; hypertension; proteinuria; arterial thrombosis; GI perforation; bleeding	Metastatic colorectal cancer in combination with FOLFIRI following progression on FOLFOX and bevacizumab; gastric cancer as a single agent or in combination with paclitaxel following progression on a fluoropyrimidine- or platinum-containing regimen; NSCLC in combination with paclitaxel for advanced disease after platinum-based treatment
Regorafenib (Stivarga)	Inhibits many membrane and intracellular kinases including *RET, VEGFR, KIT, PDGFR, FGF, TIE2, DDR2, TrkA, Eph2A, RAF-1, BRAF,* and *CSF1R*	Take with food; decreased exposure with strong inducers of CYP3A	Hepatotoxicity, fatigue, decreased appetite, hand-foot skin reaction	Previously treated metastatic colorectal cancer; gastrointestinal stromal tumor; hepatocellular carcinoma
Ribociclib (Kisqali)	Small molecule inhibitor of cyclin-dependent kinases 4 and 6; produces G1 cell cycle arrest; combined with aromatase inhibitors leads to enhanced tumor cell growth control	Metabolized in the liver by CYP3A4	Bone marrow suppression; hepatotoxicity with abnormal liver function; QT prolongation; peripheral edema; fatigue; alopecia; skin rash; hypokalemia; nausea and diarrhea; increased serum creatinine	Advanced breast cancer for patients with HR-positive, HER2-negative disease in combination with an aromatase inhibitor as initial endocrine therapy
Rituximab (Rituxan)	Monoclonal antibody directed against the B-cell surface antigen CD20	When given IV, it is taken up by B lymphocytes and then degraded throughout the body by proteolysis, with a wide-ranging serum half-life of 11-105 hr (mean 60 hr) with the first dose; there is no appreciable excretion of this polypeptide	Fever, chills, and malaise are common during administration, even with premedication with acetaminophen and diphenhydramine; other infusion-related symptoms include nausea, vomiting, flushing, urticaria, angioedema, hypotension, dyspnea, bronchospasm, fatigue, headache, rhinitis, and pain at disease sites; these symptoms are generally self-limited, improve with slowing of the infusion, and resolve after infusion; short-lived myelosuppression, abdominal pain, and myalgia are uncommon; arrhythmias and angina pectoris are rare	Relapsed or refractory low-grade or follicular, CD20-positive, B-cell lymphomas

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

TABLE 164-2 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER*—cont'd

DRUG NAME	DRUG CLASS AND/OR MECHANISM	PHARMACOKINETICS/METABOLISM	TOXICITY	INDICATIONS†
Rucaparib (Rubraca)	Inhibits poly (ADP-ribose) polymerase enzyme isoforms essential for DNA repair; increased cell killing in tumors deficient in BRCA1/2 repair pathway	Metabolized by CYP2D6 in the liver	Fatigue and dizziness; skin rash; increased cholesterol; nausea, constipation; diarrhea; blood count suppression; increased liver function tests; increased serum creatinine; weakness; dyspnea; fever	Advanced ovarian cancer in the presence of *BRCA* mutations (germline or somatic) detected by an approved diagnostic test as third-line therapy
Ruxolitinib (Jakafi)	Janus kinase signaling inhibitor	With or without food; reduce dose 50% with strong CYP3A inhibitors, moderate renal or hepatic impairment	Thrombocytopenia, anemia, bruising, dizziness, headache	Intermediate- or high-risk myelofibrosis
Sacituzumab govitecan-hziy (Trodelvy)	Trop-2–directed antibody and topoisomerase inhibitor conjugate	Individuals who are homozygous for the uridine diphosphate-glucuronosyl transferase 1A1 (UGT1A1)*28 allele are at increased risk for neutropenia	Neutropenia, severe diarrhea, hypersensitivity reactions, nausea, vomiting, anemia, alopecia, constipation, rash, abdominal pain	Metastatic triple-negative breast cancer despite at least two prior therapies
Selinexor (Xpovio)	Nuclear export inhibitor	95% protein bound; metabolized by liver	Thrombocytopenia, neutropenia, gastrointestinal toxicity, hyponatremia, serious infection, neurologic toxicity	With dexamethasone for relapsed or refractory multiple myeloma despite at least four prior therapies; or refractory diffuse large B-cell lymphoma, including disease arising from follicular lymphoma, after at least two lines of systemic therapy
Sonidegib (Odomzo)	Hedgehog pathway inhibitor that binds and inhibits Smoothened, a transmembrane protein essential for hedgehog signaling	Metabolized in the liver by CYP3A	Fatigue; alopecia; hyperglycemia; abnormal liver function tests; anemia; increased CK, muscle pain; increased serum creatinine	Locally advanced basal cell carcinoma recurrent after surgery or radiation therapy
Sorafenib (Nexavar)	Oral multikinase inhibitor that interacts with multiple intracellular (CRAD, BRAF) and cell surface kinases (KIT, FLT-3, VEGFR-2, and PDGFR); may inhibit angiogenesis	Metabolized in the liver; drug and metabolites are excreted primarily in the feces	Skin toxicity with rash and hand-foot syndrome; nausea, vomiting, anorexia, diarrhea; asthenia, pain, arthralgias; hypertension; bleeding events, especially in anticoagulated patients; cardiac ischemia; myelosuppression	Advanced renal cell carcinoma
Sotorasib (Lumakras)	Selective, orally active inhibitor that covalently binds to Cys12 of KRAS; inhibits signaling only in tumors that exhibit the KRAS-G12C mutation	Avoid proton pump inhibitors and histamine-2 receptor antagonists	Drug-induced hepatitis with increased ALT/AST requires monitoring of liver function tests; interstitial lung disease; diarrhea; musculoskeletal pain; nausea; fatigue	Adults with *KRAS-G12C*-mutated locally advanced or metastatic NSCLC
Sunitinib maleate (Sutent)	Inhibits PDGFR-A, PDGFR-B, and VEGFR1-3, stem cell factor receptor, FLT-3, CSF-1R, and the neurotrophic factor receptor; this inhibition inhibits tumor growth and metastases	Metabolized in the liver with elimination primarily in the feces; half-life is 40-60 hr for the drug and 80-110 hr for its primary metabolite	Cardiotoxicity—usually reversible; bleeding event, epistaxis most common; hypertension; myelosuppression; nausea, vomiting; rash; liver function test alterations	Advanced renal cell carcinoma; second-line therapy for GIST cell tumors; also approved for pancreatic neuroendocrine tumors
Talazoparib (Talzenna)	PARP inhibitor	Reduce dose if moderate renal impairment (creatinine clearance 30-59 mL/min)	Myelodysplastic syndrome, AML, myelosuppression, nausea, headache, vomiting, alopecia, diarrhea	Germline *BRCA*-mutated HER2-negative locally advanced or metastatic breast cancer
Tamoxifen (Nolvadex)	Nonsteroidal antiestrogen; cytostatic effects on estrogen-dependent and nondependent malignant cells	Tamoxifen has good oral bioavailability, is metabolized in the liver, and has an elimination half-life of about 7 days; neither tamoxifen nor its major metabolite is found in the bile or urine	Tamoxifen is usually very well tolerated; constitutional symptoms are most prevalent and usually dose limiting; hot flashes, sweating, mood changes, weight gain or loss, and stomach upset are most common; nausea, vomiting, diarrhea, and constipation are less common; menstrual changes, including significant vaginal bleeding, are uncommon; venous thromboembolism, myelosuppression, and retinopathy are rare	Approved for the treatment of breast cancer, generally in postmenopausal patients or those with ER+ tumors; the same dose has been approved for chemoprevention of breast cancer in high-risk individuals; higher doses are used for melanoma and pancreatic cancer
Tazemetostat (Tazverik)	Methyltransferase inhibitor	Avoid strong and moderate CYP3A inhibitors and strong and moderate CYP3A inducers	Fatigue, nausea, vomiting, constipation, upper respiratory tract infection, musculoskeletal pain, abdominal pain	Metastatic or unresectable locally advanced epithelioid sarcoma, relapsed or refractory follicular lymphoma with an EZH2 mutation or no alternative treatment options

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

Temozolomide (Temodar)	Atypical alkylator (semiselective DNA methylator) drug sharing the same active metabolite as dacarbazine, MTIC but, unlike dacarbazine, is spontaneously converted to MTIC and also penetrates the blood-brain barrier effectively	Temozolomide had good bioavailability, enhanced by an empty stomach; after absorption into the blood stream, it is spontaneously converted to the active moiety MTIC; peak plasma concentrations occur in about 1 hr; the elimination half-life is about 1.8 hr; parent drug, MTIC, and other metabolites are eliminated in the urine	Myelosuppression is expected and dose-limiting; it may be cumulative; nausea is common but generally mild and treatable; headache and fatigue are common; rash or other cutaneous reactions are uncommon; infections are common in this population, and some are probably caused by immunosuppression that is known to occur with temozolomide	Approved for treatment of recurrent high-grade astrocytomas; used commonly for other gliomas and also for metastatic melanoma
Temsirolimus (Torisel)	Inhibitor of mTOR	Antihistamine pretreatment is recommended; dose reduction is required in patients with mild hepatic impairment; strong inducers of CYP3A4/5 and inhibitors of CYP3A4 may affect concentrations of the primary metabolite, sirolimus; if alternatives cannot be used, dose modifications are recommended	Hypersensitivity/infusion reactions (including some life-threatening and rare fatal reactions) can occur early in the first infusion; patients should be monitored throughout the infusion; monitor for symptoms or radiographic changes of ILD; if ILD is suspected, discontinue drug, and consider use of corticosteroids and/or antibiotics; bowel perforation may occur; evaluate fever, abdominal pain, bloody stools, and/or acute abdomen promptly; elderly patients may be more likely to experience certain adverse reactions, including diarrhea, edema, and pneumonia	Advanced renal cell carcinoma
Tepotinib (Tepmetko)	Tyrosine kinase inhibitor that blocks signaling through a *MET* exon 14 skipping mutation	Avoid use with strong CYP3A and P-gp inhibitors; metabolized in the liver and excreted in feces	Edema; fatigue; nausea; diarrhea; interstitial lung disease; hepatotoxicity	NSCLC with *MET* exon 14 skipping mutation
Tisagenlecleucel (Kymriah)	Anti-CD19 CAR–T-cell immunotherapy	No contraindications	Cytokine release syndrome; neurologic toxicity	ALL B-cell precursor type refractory to primary therapy
Topotecan (Hycamtin), hycamptamine	Semisynthetic camptothecin molecule; an inhibitor of topoisomerase I, which is required by cells for both transcription and replication	After IV administration, the drug is not extensively metabolized, and it has an elimination half-life of about 3 hr; a significant portion of the drug is excreted unchanged in the urine	Myelosuppression, especially leukopenia, is expected and dose limiting; thrombocytopenia and anemia are common but mild; nausea, vomiting, and diarrhea are common but usually not severe; headache, fever, fatigue, anorexia, malaise, and elevated liver function tests are also common; hypertension, tachycardia, urticaria, renal insufficiency, hematuria, neuropathy, and mucositis are uncommon	Approved for the treatment of refractory, relapsed ovarian carcinoma and for relapsed small cell lung cancer; also used in myeloid leukemias
Trabectedin (Yondelis)	Alkylating agent that binds the minor groove of DNA-producing adducts	Avoid strong CYP3A inhibitors or inducers	Neutropenic sepsis; rhabdomyolysis; hepatotoxicity; cardiotoxicity; fetal harm	Unresectable or metastatic liposarcoma or leiomyosarcoma after prior anthracycline therapy
Trametinib (Mekinist)	Selective inhibitor of mitogen-activated extracellular kinase (MEK) 1 and 2; decreases cellular proliferation; combination with BRAF inhibitors increases inhibition of MAPK pathway	Deacetylated and glucuronidated in liver; no dose adjustments for mild renal or hepatic dysfunction	Cardiovascular (hypertension, decreased LVEF); acneiform rash and palmar-plantar erythrodysesthesia; diarrhea; anemia; peripheral edema	Advanced melanoma in patients with *BRAF* V600E or V600K mutations alone or in combination with dabrafenib; metastatic NSCLC with *BRAF* V600E mutation in combination with dabrafenib
Aldo-trastuzumab emtansine (Kadcyla)	Antibody-drug conjugate targeting HER2; composed of trastuzumab covalently linked to a maytansine derivative (DM1) with microtubule inhibitory properties; after binding to HER2, it is internalized with release of DM1 and tubulin disruption	Metabolized in the liver by CYP3A4	Hepatotoxicity; left ventricular dysfunction; infusion reaction; pneumonitis; blood count suppression	HER2-positive metastatic breast cancer previously treated with trastuzumab and a taxane
Fam-trastuzumab deruxtecan-nxki (Enhertu)	HER2-directed antibody and topoisomerase inhibitor conjugate	Intravenous infusion only, but not with sodium chloride	Interstitial lung disease, neutropenia, left ventricular dysfunction, nausea, vomiting, fatigue, alopecia, constipation, anemia, diarrhea, thrombocytopenia	Unresectable or metastatic HER2-positive breast cancer despite two or more prior anti-HER2-based regimens

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

TABLE 164-2 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER*—cont'd

DRUG NAME	DRUG CLASS AND/OR MECHANISM	PHARMACOKINETICS/METABOLISM	TOXICITY	INDICATIONS†
Trastuzumab (Herceptin)	Genetically engineered humanized mouse monoclonal antibody directed against HER2/neu growth factor receptor that is overexpressed in many invasive breast carcinomas; mechanism of action for clinical activity in breast cancer is unknown but may be complement-mediated cell lysis, antibody-dependent cellular cytotoxicity, or induction of apoptosis	Binding studies show strong binding to cells overexpressing HER2/neu molecules; very little else is known regarding the distribution and metabolic fates of this molecule; half-life should be very short with minimal distribution outside the vascular compartment and minimal clearance by kidneys or liver (similar to other monoclonal agents)	Common toxicities include acute fever, chills, nausea, vomiting, and headache; trastuzumab seems to worsen leukopenia, anemia, and diarrhea when given with chemotherapy compared with chemotherapy alone; also, trastuzumab may have uncommon acute cardiotoxicity, which may add to the more common anthracycline-induced cardiotoxicity; therefore, the use of trastuzumab with doxorubicin is not indicated by the FDA	Approved for HER2/neu overexpressing metastatic or locally advanced breast cancer; has shown clinical benefit as a single agent and in conjunction with paclitaxel-based chemotherapy; also approved for gastric cancer
Tucatinib (Tukysa)	HER2 tyrosine kinase inhibitor	Avoid strong CYP3A inducers, moderate CYP2C8 inducers, strong CYP2C8 inhibitors, CYP3A substrates, and P-gp substrates	Diarrhea, hepatotoxicity	In combination with trastuzumab and capecitabine for advanced unresectable or metastatic HER2-positive breast cancer despite other anti-HER2 regimens
Umbralisib (Ukoniq)	Oral kinase inhibitor active against PI3K-delta and casein kinase CK1-epsilon	No dosage reduction required for mild renal or hepatic dysfunction; rapidly absorbed and excreted predominantly in feces	Neutropenia; diarrhea; noninfectious colitis; hepatotoxicity; cutaneous reactions	Marginal zone lymphoma relapsed or refractory following at least one prior anti–CD20-based regimen; follicular lymphoma relapsed or refractory after at least three lines of systemic therapy
Vandetanib (Caprelsa)	Kinase inhibitor	The concomitant use of known strong CYP 3A4 inducers may reduce drug levels of vandetanib and should be avoided. No clinically significant drug interaction was shown with vandetanib and the potent CYP 3A4 inhibitor, itraconazole. The administration of vandetanib with agents that may prolong the QT interval should be avoided. In total, 18% of medullary thyroid cancer patients treated with vandetanib were age 65 yr or older, and 3% were 75 yr and older. No overall differences in safety and efficacy were observed between elderly and younger patients. No adjustment in starting dose is required for patients over 65 yr of age. There are limited data for patients over the age of 75 yr. Limited data for renal or hepatic impairment point toward dose reductions	QT prolongation: sudden death has been reported. Monitor electrocardiograms and levels of serum potassium, calcium, magnesium, and TSH at baseline, 2-4 wk and 8-12 wk after starting treatment, and every 3 mo thereafter and following dose adjustments. Dose reduction as appropriate. Stevens-Johnson syndrome resulting in death has been observed. Severe skin reactions may prompt permanent discontinuation of the drug. Interstitial lung disease resulting in death has been reported. Interrupt dosing and investigate unexplained dyspnea, cough, and fever. Appropriate measures should be taken for ILD. Ischemic cerebrovascular events, hemorrhage, heart failure, diarrhea, hypothyroidism, hypertension, and reversible posterior leukoencephalopathy syndrome have been observed. Other common adverse events: diarrhea, rash, acne, nausea, hypertension, headache, fatigue, upper respiratory tract infections, decreased appetite, and abdominal pain. The most common laboratory abnormalities were decreased calcium, increased ALT, and decreased glucose	Thyroid cancer unresectable locally advanced or metastatic
Vemurafenib (Zelboraf)	Inhibits V600E serine-threonine and other kinases	Take with or without food; inhibits CYP1A2, 2D6; enhances CYP3A	Produces cutaneous squamous cell carcinoma, hypersensitive and dermatologic reagins, QT prolonged, liver lab abnormalities	Metastatic *BRAF*+ melanoma
Venetoclax (Venclexta)	BCL-2 inhibitor	Take with meal and water; prophylaxis for tumor lysis syndrome with anti-hyperuricemic agents and adequate hydration; do not use strong inhibitors of CYP3A at initiation and during ramp-up phase	Tumor lysis syndrome; neutropenia; fetal harm; diarrhea, nausea; anemia; upper respiratory tract infection	CLL with 17p deletion, per FDA-approved test, after at least one prior therapy

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

Vinorelbine (Navelbine), 5′-noranhydrovinblastine, NVB	Semisynthetic vinca alkaloid; inhibitor of tubulin polymerization and thereby mitosis; G2-phase specific	Metabolized by the liver and has an elimination half-life of about 24 hr; excretion is predominantly in the bile	Vinorelbine is a mild vesicant, requiring extravasation precautions; myelosuppression, mostly leukopenia, is expected and dose limiting; significant nausea and vomiting are uncommon; neurotoxicity in the form of neuropathy is less common and milder than that seen with vincristine; tumor pain during administration has been reported; acute reaction such as dyspnea, chest pain, and wheezing have occurred during administration and may be prevented by premedication with corticosteroids	Approved for the treatment of relapsed metastatic breast cancer and for NSCLC as a single agent or combined with a platinating agent
Vismodegib (Erivedge)	Hedgehog pathway inhibitor	Safety and effectiveness have not been established for hepatic or renal impairment; absorption is saturable as evidenced by the lack of dose-proportional increase in exposure after a single dose of 270 mg or 540 mg vismodegib; may be taken without regard to meals because the systemic exposure of vismodegib at steady state is not affected by food	The most common adverse reactions (incidence of ≥10%) are muscle spasms, alopecia, dysgeusia, weight loss, fatigue, nausea, diarrhea, decreased appetite, constipation, arthralgias, vomiting, and ageusia. Advise patients not to donate blood or blood products while receiving vismodegib and for at least 7 mo after the last dose.	Metastatic basal cell carcinoma or locally advanced basal cell carcinoma that has recurred following surgery or patients who are not candidates for surgery and who are not candidates for radiation
Zoledronic acid (Zometa)	Bisphosphonate inhibitor of bone metastases	Zoledronic acid is poorly absorbed by the GI tract and is therefore given as an IV infusion; it is not metabolized and is excreted by the kidneys; it has a plasma terminal elimination half-life of about 150 hr	Zoledronic acid is generally well tolerated; the most common infusional adverse effect is fever, which is usually mild and treatable; nausea and constipation are also common; dyspnea, fatigue, diffuse pain, rash, and headache are uncommon; renal insufficiency is uncommon and generally reversible after discontinuation of the drug, but it is more likely with higher doses than with the approved and recommended 4-mg dose	Approved for treatment of hypercalcemia of malignancy and for prevention of pathologic fractures in multiple myeloma and solid tumors with known bone metastases

*Full listing of all FDA-approved agents appears online at https://www.cancer.gov/about-cancer/treatment/drugs/cancer-type.

†Note that indications may change based on the results of clinical trials and other data.

ABMT = autologous bone marrow transplantation; AC = accelerated phase; ADCC = antibody-dependent cell-mediated cytotoxicity; ADP = adenosine diphosphate; AIDS = acquired immunodeficiency syndrome; ALK = anaplastic lymphoma kinase; ALL = acute lymphoblastic lymphoma; ALT = alanine aminotransferase; AML = acute myelogenous leukemia; AST = aspartate aminotransferase; AUC = area under the curve; BC = breast cancer; BID = twice a day; CK = creatine kinase; CLL = chronic lymphocytic leukemia; CML = chronic myelogenous leukemia; CNS = central nervous system; CP = chronic phase; CTCL = cutaneous T-cell lymphoma; CTLA-4 = cytotoxic T-lymphocyte antigen 4; CYP = cytochrome; D5W = 5% dextrose in water; dATP = deoxyadenosine triphosphate; DMHHT = demethyl-homoharringtonine; DVT = deep vein thrombosis; ECG = electrocardiogram; EGFR = epidermal growth factor receptor; ER = estrogen receptor; FAMP = fludarabine monophosphate; FDA = Food and Drug Administration; 5-FU = 5-fluorouracil; FSH = follicle-stimulating hormone; G6PD = glucose-6-phosphate dehydrogenase; G-CSF = granulocyte-colony stimulating factor; GGT = gamma-glutamyltransferase; GI = gastrointestinal; GIST = gastrointestinal stromal tumor; GM-CSF = granulocyte-macrophage colony-stimulating factor; GnRH = gonadotropin-releasing hormone; GVHD = graft-versus-host disease; HDAC = histone deacetylase; HIV = human immunodeficiency virus; HMM = hexamethyl melamine; HR-positive = hormone receptor positive; HRT = hormone replacement therapy; HSC = hematopoietic stem cell; IFN = interferon; IGF = insulin-like growth factor; IgG2 = immunoglobulin G2; IL = interleukin; ILD = interstitial lung disease; IM = intramuscular; INR = International Normalized Ratio; IV = intravenous; LDH = lactate dehydrogenase; LH = luteinizing hormone; LHRH = luteinizing hormone–releasing hormone; LVEF = left ventricular ejection fraction; MAPK = mitogen-activated protein kinase; MDS = myelodysplastic syndrome; MET = mesenchymal epithelial transition factor receptor; MOPP = mechlorethamine, vincristine, procarbazine, and prednisone; MSI = microsatellite instability; MTIC = 5-(3-,ethyltriazen-1-yl)imidazole-4-carboxamide; mTOR = mammalian target of rapamycin; NHL = non-Hodgkin lymphoma; NSAIDs = nonsteroidal anti-inflammatory drugs; NSCLC = non–small cell lung cancer; PARP = poly (ADP-ribose) polymerase; PDGF = platelet-derived growth factor; PD-L1 = programmed death ligand 1; PE = pulmonary embolism; P-gp = P-glycoprotein; PI = phosphoinositide; PNET = progressive neuroendocrine tumor; PO = by mouth; PT = prothrombin time; RANK = receptor activator of nuclear factor–κB; RCC = renal cell carcinoma; SCLC = small cell lung cancer; SEGA = subependymal giant cell astrocytoma; SQ = subcutaneous; TID = three times a day; TNF = tumor necrosis factor; TSC = tuberous sclerosis; TSH = thyroid-stimulating hormone; UGTs = UDP-glucuronosyltransferases; ULN = upper limit of normal; VEGF = vascular endothelial growth factor.

As indicated throughout this chapter, the pace has accelerated for approvals of new drugs and new indications. Updated information should be checked on the FDA website (www.fda.gov/drugs) or other authoritative sources.

small cell lung cancer and non–small cell lung cancer is critical for treatment. For breast cancer (Chapter 183), the treating physician is interested in a variety of factors, such as histology, tumor grade, the presence (and its degree) or absence of estrogen and progesterone receptor proteins, the presence of HER2/neu overexpression, and other molecular characteristics. The rapidly increasing sophistication of molecular diagnostics has also greatly improved the potential to localize cancers of unknown primary origin (see the section Cancer of Unknown Origin later in this chapter).

Staging and Multidisciplinary Evaluation

After a tissue diagnosis has been established, careful staging is required to determine the extent of disease. The American Joint Committee on Cancer staging system, which is the standard in the United States, is based on the TNM (tumor, node, metastasis) system that is anatomically and pathologically based. The approach to staging from a clinical perspective depends on the type of cancer, but it commonly includes computed tomography (CT), magnetic resonance imaging (MRI), and, increasingly, positron emission tomography (PET) and PET-CT. These studies are supplemented by routine hematologic and chemistry profiles, tumor markers, and molecular characterization (when appropriate), as well as by bone marrow aspiration and biopsy in some cases.

The goal of tumor staging is to define the extent of a patient's disease. Tumor stage provides critical prognostic information that will inform the therapeutic approach that is most appropriate. Accurate staging involves delineating the magnitude of the tumor determined by imaging procedures, as well as confirming the pathologic limits of disease spread from tissues removed at surgery. In essence, for most solid tumor patients, the tumor stage will establish whether the treatment will focus on a local (usually confined to an organ), regional, or disseminated pattern of malignancy and can determine whether the expected outcome of therapy is curative or palliative. Conversely, hematopoietic malignancies are often disseminated at diagnosis and demand their own prognostic classifiers.

The focus of the staging evaluation is to identify potential sites of metastases and to establish indicator lesions with which to monitor therapy. For most solid tumors, CT scans can accomplish both goals; however, in some circumstances, other imaging modalities are more appropriate for therapeutic monitoring (e.g., MRI when central nervous system [CNS] metastases are likely [e.g., small cell lung cancer], or combined PET/CT imaging to establish that a given lesion is likely to be metabolically active and malignant, or in diseases in which early metabolic responses to treatment can be confirmed [such as for gastrointestinal stromal tumors]). In patients with established advanced disease, indicator lesions for therapeutic monitoring should be carefully chosen prior to the initiation of treatment, be well documented in the medical record, and be evaluated with the minimum frequency of imaging procedures required for accurate follow-up, consistent with evidence-based medical practice or the clinical protocol on which the patient is entered.

The consulting medical oncologist may often be advised by a local tumor board composed of other medical, surgical, and radiation oncologists, pathologists, radiologists, and members of the cancer care team (oncology nurses, social workers, and palliative care specialists). In such a multidisciplinary environment, the patient's overall prognosis can be reviewed and alternatives for care, including standard therapy, possible clinical trials, a second opinion, or no treatment, can be considered. The outcome of such an evaluation is usually viewed by patients and families as an important component in the coordinated development of an overall plan for either further diagnostic procedures or therapy. Finally, many oncologists actively participate in clinical trials that may make investigational drugs or other investigational procedures available for patients, or they may suggest referral to a tertiary cancer center where disease-specific or molecularly defined clinical trials are available.

TREATMENT

Therapeutic Plan

Intention of Treatment

Based on the multidisciplinary evaluation of an accurately staged patient, the chosen intent of treatment may be curative or palliative. Whether or not this choice is made during a formal tumor board or multidisciplinary case conference, clarity must be reached regarding the specific choice of therapeutic options (and their potential risks and benefits, overall goals, and alternatives) when considered in the context of the wishes of the patient and family. This issue is particularly relevant when the side effects of treatment are substantial (such as for the multidisciplinary management of non–small cell lung cancer or esophageal cancer). For cancers that are amenable to surgery, resection is often an initial alternative if the patient is a suitable candidate for anesthesia and is otherwise in acceptable condition in terms of comorbid illnesses (Chapter 399). Determination of the patient's performance score (see Table 164-1) is a simple means of assessing functional status. If life expectancy is limited or if the patient is not a good candidate for surgery, more limited approaches to palliative radiation or systemic therapy may be appropriate. Substantial data indicate that the extent of surgery required for an optimal long-term outcome may be reduced for certain solid tumors through the use of presurgical, so-called "neoadjuvant" chemotherapy, often as part of an "organ-sparing" approach. Concomitant or sequential multimodality treatments also have the potential to produce long-term disease-free remissions. When the best therapeutic outcomes require the combined skills of surgical, radiation, and medical oncologists, the need for coordination of care among a variety of specialists becomes paramount and the use of predefined treatment regimens critical.

Therapeutic Paradigm and Therapeutic Index

The therapeutic paradigm in oncology, although still directed at improving the multidisciplinary care model, has begun to change from one focused on delivering treatments at the "maximally tolerated dose" for normal tissues to therapy that is personalized based on both the molecular characteristics of the patient's tumor as well as any individual germline features that could modify treatment tolerance (Chapter 166). Based on the rapid expansion of information regarding somatic mutations in human malignancies and the ability to produce therapeutic molecules that can target specific defects in tumoral DNA repair, growth factor signaling, energy balance, or immunocompetence, for example, the current approach to cancer therapeutics involves the use of predictive molecular markers ("biomarkers") whenever possible to guide all modalities of cancer care for the benefit of unique cancer patients. Hence, the focus of oncologists is on the elaboration of treatments that can be administered with a high therapeutic index, defined as the comparison of the amount of treatment that is effective as compared with the amount that causes toxicity. The goal of precision cancer medicine therapy is to minimize toxicity to normal tissues and to preserve quality of life by advancing therapies or procedures that are targeted only to the specific molecular dependencies of the patient's tumor.

Surgical Therapy

Surgery is used to biopsy a suspected lesion, remove the primary tumor, bypass obstructions, provide palliation, and prevent cancers in patients at very high risk because of genetic predispositions or chronic inflammatory states. Surgical staging also establishes the extent of disease. For example, patients with ovarian cancer (Chapter 184) benefit from surgical "debulking" to remove all visible disease, leave minimal residual tumor, and thereby enhance the effectiveness of systemic treatment. Placement of a venous access device at the time of surgery, if considered proactively, may eliminate the need for a second procedure.

Risk-reducing bilateral mastectomy and risk-reducing salpingo-oophorectomy are options for the primary prevention of breast (Chapter 183) and ovarian cancers in individuals who are genetically predisposed to these malignancies. Although these operations provide considerable efficacy in terms of cancer prevention, they can be associated with profound adverse physical and psychosexual effects. Decisions to proceed with such risk-reducing surgery are complex and emotionally charged. Patients require clearly understandable information and counseling, as well as adequate time and support to think through their options.[4]

Surgery remains the most common method to cure localized cancers such as breast cancer (Chapter 183), colorectal cancer (Chapter 179), and lung cancer (Chapter 177), but it is limited by the location of the tumor, its extension, and distant metastases.[A1] Even if a tumor cannot be removed, surgical biopsy provides confirmation of the diagnosis and additional tissue for molecular analysis. Occasionally, an obstructing lesion can be bypassed to provide palliation.

In specific circumstances when the primary tumor has been controlled, removal of a single metastasis (metastasectomy) can result in long-term survival; an example is resection of a solitary liver metastasis found at the time of colectomy for colorectal cancer (Chapter 179). A variety of surgical techniques, such as radiofrequency ablation or cryoablation, can also be used to treat hepatic metastases in carefully selected patients. Adjuvant chemotherapy is often given after surgery in this situation to treat microscopic metastases.

The careful application of reconstructive surgery after a disfiguring procedure is critical to long-term physical and emotional well-being. Examples include postmastectomy breast reconstruction (Chapter 183) and plastic surgical procedures to correct deformities following head and neck surgery (Chapter 176).

Radiation Therapy

Ionizing radiation (Chapter 18) can be delivered using beams of high-energy rays, known as *teletherapy*, via a linear accelerator; by brachytherapy, through the application of sealed radioactive implants, seeds, wires, or plaques; and intravenously by using radioisotopes, either directly or attached to antibodies or other targeting molecules.[5] Radiation interacts with water molecules to induce free radical species, including hydroxyl radicals, which damage DNA, proteins, and lipid membranes, thereby leading to cell death. As with chemotherapy, radiation therapy is most effective against rapidly dividing cells that are well oxygenated. Radiation-induced DNA damage may also increase sensitivity to chemo- or immunotherapy.

The utility of radiation therapy is limited by the inapparent extension of disease outside a local treatment field, by the location of tumors next to normal structures that must be preserved, and by the presence of distant metastases. Normal tissue tolerance, which varies across different organs and tissues, often prevents the use of radiation doses that could uniformly eradicate cancers. Radiation therapy is also limited by tumor hypoxia: large, bulky tumors are frequently relatively radioresistant, whereas well-oxygenated tumors can be more effectively treated at lower doses. In addition to acute radiation-related toxicities (Chapter 18), late effects of radiation therapy include second malignancies, such as breast cancers that may occur decades after administering thoracic radiation fields during curative treatment for Hodgkin disease.

Radiation therapy can be used as primary treatment, as part of multimodality therapy, in the adjuvant setting, and for palliation. As a single modality, radiation therapy can be curative for early-stage malignancies such as laryngeal cancer (Chapter 176), cervical cancer (Chapter 184), and prostate cancer (Chapter 186). Breast-conserving surgery (Chapter 183) requires the use of radiation to treat the remaining breast. Partial irradiation techniques using three-dimensional planning with external beam radiation can be used in selected patients with appropriately placed and sized breast cancers. For certain patients who have localized prostate cancer (Chapter 186), implanted radioactive seeds of gold or palladium offer an alternative to surgery or external beam radiation therapy.

Intensity-modulated radiation therapy (IMRT) permits more exact tailoring of the dose to the target, thereby reducing damage to the surrounding normal tissues. Stereotactic radiation therapy or gamma knife techniques allow the treatment of primary or metastatic brain tumors (Chapter 175) measuring up to 3 cm with enhanced accuracy, thereby minimizing damage to normal brain. An analogous approach may help patients whose primary tumor has been controlled and who have a limited number of metastatic lesions. Particle-based treatment with protons can deliver higher radiation doses locally. However, no randomized studies demonstrate its superiority over other approaches that use computational techniques (e.g., IMRT) to improve the specificity of the delivery of radiation. However, proton therapy is generally recommended for some uveal melanomas, base-of-skull tumors, and a few pediatric malignancies.

Low- to moderate-dose palliative radiation is used to ameliorate symptomatic cancer when cure is no longer the goal. For instance, radiation therapy can improve symptoms from brain metastases (Chapter 175), relieve pain from bone lesions (Chapter 187), relieve some obstructing lesions, and sometimes improve hemoptysis caused by lung cancer (Chapter 177) or bleeding from a gynecologic malignancy (Chapter 184). Bone-seeking radioisotopes of samarium, strontium, or radium may relieve pain from bone metastases in prostate cancer (Chapter 186) or breast cancer (Chapter 183).

Systemic Therapy

Cancer Pharmacology

Principles

The fundamental goal of cancer pharmacology is the development of treatments that can be matched to the intrinsic sensitivity of specific tumors and that can be delivered in concentrations that affect the molecular target of interest with an acceptable therapeutic index. Three properties of all cancer therapeutic agents underlie their clinical utility: pharmacogenetics of the drug (how the germline or somatic expression of genes alters normal tissue toxicity or antitumor efficacy); action of the drug (pharmacodynamics, or what the drug does to the tumor/body); and delivery of the drug (pharmacokinetics, or what the body does to the drug).

Pharmacogenetics

Pharmacogenetics, which is the study of inherited interindividual differences in drug disposition and effects, is important in cancer therapy because genetic polymorphisms in drug-metabolizing enzymes may be responsible for the variations in efficacy and toxicity that are observed with many chemotherapeutic agents. Drugs potentially affected by polymorphisms include the thiopurines, 5-fluorouracil, irinotecan, taxanes, and platinum agents. In patients who are heterozygous or homozygous for deficiencies in metabolizing enzymes, toxicity can be dramatically enhanced. Testing for pharmacogenetic variations that predict for altered normal tissue tolerance is currently available for thiopurines and irinotecan.

Molecular Targeting and Pharmacodynamics

Molecular diagnostic testing, which began with testing to predict the antitumor activity of hormonal and anti-HER2 therapeutics, is now relevant to a wider range of tumors for which molecularly targeted and immunotherapeutic anticancer agents are useful only after demonstration of specific molecular abnormalities.[6] Examples of such diagnostic/drug pairs include the prototypical *BCR-ABL* mutation in chronic myelogenous leukemia and imatinib; *EGFR* mutations in lung adenocarcinomas and erlotinib; *ALK* tyrosine kinase translocations in lung adenocarcinomas and crizotinib; $BRAF^{V600E}$ mutations in melanoma and vemurafenib, *NTRK* fusions and larotrectinib; and *KRAS* mutations in various solid tumors. Molecular targeting can also involve the expression of mismatch repair genes and immunologic checkpoint inhibitors.

Pharmacokinetics and Drug Delivery

Dose selection in oncology is a critical issue, primarily because anticancer agents have among the smallest therapeutic ratios in all of medicine. When tumors are responsive to treatment, higher doses may or may not be more effective but are likely to be more toxic to normal tissues. The clearance of a drug from both the systemic circulation and, potentially, from specific physiologic compartments (CNS, pleural, or peritoneal effusions), as evidenced by its systemic exposure, is the most important determinant of the recommended dose for a particular patient. Clearance, which is a composite of all the routes and mechanisms by which the drug can be eliminated from the body, determines dosing and dose adjustments in the face of changes in drug metabolism, transport, or altered organ function. Although a clear understanding of drug half-lives is important to establish initial dosing schedules, systemic exposure will be the actual determinant of the dose of drug that can be safely administered. Another aspect of drug delivery is the use of body surface area dosing versus flat dosing (using fixed amounts of a drug) in oncologic practice. Although dosing based on body surface area has a long history in oncology, very little data support this approach; for most agents in common use, empirically determined pharmacokinetic variability from patient to patient is far greater than what could reasonably be determined by dosing based on weight or surface area.

Routes of Drug Dosing

Although some agents require intravenous administration, oral agents that permit outpatient therapy are increasingly being used. The oral route of administration highlights drug delivery issues, such as adherence (does the patient take his/her medication), variability in absorption (due to food effects), emesis prior to drug absorption, first-pass metabolism in the liver or intestine, and difficulties in swallowing. For example, whether the orally administered anti-HER1/2 drug lapatinib is taken with food or on an empty stomach can alter its absorption by as much as 10-fold.

In addition to intravenous or oral dosing, anticancer drugs may be used for intrathecal delivery (to overcome the blood-brain barrier) in the treatment or prevention of meningeal spread of leukemia; for intravesicle therapy of early-stage bladder cancer; for intra-arterial delivery of fluoropyrimidines or other agents to treat hepatic metastases from colon cancer or hepatocellular carcinoma; and for intraperitoneal administration of drugs such as platinum agents for ovarian cancer therapy. In almost all cases, administration of anticancer agents by other than the oral or intravenous routes requires intimate involvement of an oncologic specialist.

Clinical Trials

Clinical trials in oncology are defined by the steps in which new diagnostic approaches, therapeutic agents, or procedures are tested to determine whether they will become part of the standard care for cancer patients. During interventional (rather than observational) clinical trials, specific treatments or procedures are assigned to participants, and the effects of the interventions are measured. For trials of new oncologic drugs, the U.S. Food and Drug Administration (FDA) recognizes several states in the drug development process. Exploratory studies of new drugs examined for the first time in humans (phase 0 trials) may be conducted in a limited number of patients to define a drug's mechanism of action or biodistribution and to guide subsequent dosing in larger studies. Phase I trials use a variety of dose-escalation strategies to define the maximum dose that can be safely administered to humans and the most appropriate schedule for drug administration, as well as the pharmacokinetic and pharmacodynamic profile of the drug. Phase II trials often enroll 50 to 150 subjects and focus on testing the drug to determine its effectiveness and side effect profile in a specific malignancy (or for a specific cancer-related molecular abnormality). If a drug demonstrates anticancer activity in a phase II study, phase III trials are performed to compare the usefulness of an investigational treatment to a control group of patients who receive the standard of care; patients in most phase III studies are randomly assigned to the new or standard treatment to avoid a biased assessment of the results of the study. Finally, after approval of a new drug by the FDA, usually based on the results of phase III studies, phase IV trials may be performed to collect safety information on larger patient populations to define the prevalence of side effects that may be rare but serious.

Traditionally designed phase II trials test one treatment at a time in heterogenous groups of patients and are therefore not an efficient use of clinical resources. Adaptive multigroup clinical trials have the potential to answer several questions simultaneously and more efficiently by matching targeted therapies to the cancer patients who are most likely to benefit from them. Some trials for breast cancer, for example, use a platform to compare up to 12 experimental therapies with a single, common control group in subgroups of breast cancer patients with 10 distinct biomarker signatures.[7] New drugs enter the platform as they emerge from phase I testing and exit the platform with an estimate of the chances of future success in a phase III trial of prespecified size. Despite some significant unresolved issues, the adaptive strategy is likely to become an important addition to the inventory of clinical trial designs. Another approach is so-called master protocols, which evaluate one or more agents against a specific molecular characteristic possessed by the tumor rather than its histology.[8]

Drug Interactions

Many drug interactions affect the toxicity profile of anticancer agents, usually because concomitant administration of a second drug changes the clearance of the cancer therapeutic, thereby potentially enhancing side effects if the clearance is decreased or diminishing efficacy because of reduced drug exposure.

Most often these interactions occur because one drug affects the metabolism of the other by inhibiting or enhancing the activity of cytochrome P-450 isoforms (such as CYP3A) in the liver. This interaction is particularly true for agents administered orally, such as imatinib, crizotinib, enzalutamide, pazopanib, and lapatinib. Concomitant drug-related as well as pharmacogenetic variations in proteins that affect the transport of anticancer agents across tumor and normal cell membranes, such as efflux pumps, also affect the sensitivity or resistance of many classes of cancer drugs. For example, certain drugs that are well-known inducers of hepatic metabolism (e.g., phenytoin and rifampin) also induce the expression of drug transport proteins.

Combination Therapy

Virtually all curative chemotherapy regimens developed for hematologic malignancies or solid tumors use combinations of active agents. Combination chemotherapy is usually superior to the use of single agents in adjuvant and neoadjuvant therapy as well. The improved results achieved by combination chemotherapy can be explained in several ways. Mechanisms of resistance to any particular single agent are almost always present in the tumor genome at diagnosis, even in clinically responsive tumors. Tumors that are initially "sensitive" to systemic therapy rapidly acquire resistance to single agents, either as a result of selection of a preexisting clone of resistant tumor cells or because of a variety of potential acquired molecular changes (e.g., increased drug efflux, enhanced DNA repair, insensitivity to apoptosis) that lead to clinical drug resistance. Combination therapy may address these phenomena by providing a broader range of mechanisms of drug action against initially resistant tumor cells, thereby preventing or slowing the selection of resistant clones.

The development of combination systemic therapy regimens follows a set of principles (Table 164-3). For standard cytotoxic agents, each drug in the combination must be active against the tumor, and all drugs must be given at an optimal dose and on an appropriate schedule. The drugs should have different mechanisms of antitumor activity as well as different toxicity profiles, and the drugs should be given at consistent intervals for the shortest possible treatment time. The use of molecularly targeted agents in combination requires that each agent engages its specific target and that the combination enhances the inhibition of the tumor's growth. Toxicities of targeted agents should be moderate to allow prolonged administration and maximum target inhibition.

Therapeutic Settings

Systemic therapy is used in a variety of settings with or without and before, during, or after surgery and radiation therapy (Table 164-4). Considerable experimental evidence suggests that cancers are most sensitive to chemotherapy during early stages of growth because of higher growth fractions and shorter cell cycle times. As a result, a given dose of a cytotoxic drug may exert a greater therapeutic effect against a rapidly growing tumor than against a larger quiescent tumor.

Neoadjuvant therapy, also called primary or induction systemic therapy, is used before surgery or radiation therapy to decrease the size of locally advanced cancers, thereby permitting a more complete surgical resection or eradication of undetectable metastases. Neoadjuvant therapy also affords an opportunity to evaluate the effectiveness of treatment by histologic and molecular analysis of resected tissue. This approach is most often used for locally advanced breast cancer (Chapter 183).

Organ-sparing therapy is another use of chemotherapy, radiation therapy, or both to salvage organs that would have been surgically removed if cure were the intended result. This technique is often effective in patients with cancers of the larynx (Chapter 176), esophagus (Chapter 178), and anus (Chapter 179).

Adjuvant chemotherapy is used in patients whose primary tumor and all visible evidence of cancer (e.g., regional lymph nodes) have been surgically removed or treated definitively with radiation, but in whom the risk of recurrence is high because of involved lymph nodes or certain morphologic or biologic characteristics of the cancer. Common examples include cancers of the breast (Chapter 183) and colon (Chapter 179). The typical end points of chemotherapy, such as shrinkage of measurable tumor on serial radiographic studies, are not available in this situation; instead, relapse-free survival and overall survival are the principal measures of a treatment's effect. The benefit of adjuvant therapy cannot be assessed in individual patients who receive it, so decisions about its use must be based on evidence from clinical trials.

Assessment of Response

Assessment of the response to therapy (usually performed using RECIST [Response Evaluation Criteria in Solid Tumors]) depends largely on the tumor's size, as determined by either direct measurement or diagnostic imaging studies, using predefined categories. The categories of response are "complete response," with total absence of tumor and correction of tumor-associated changes measured twice at least 4 weeks apart; "partial response," defined as 30% or greater reduction in the sum of the longest diameters of up to five target lesions per organ, confirmed by repeat measurement 4 weeks later; "progressive disease," characterized by either 20% or greater increase over the smallest sum of the longest diameters of target lesions or the development of new tumors; and "stable disease," defined as meeting criteria for neither partial response nor progressive disease. Leukemias are assessed by bone marrow biopsies and molecular diagnostic tests for residual disease, and multiple myeloma is typically assessed by the measurement of monoclonal proteins, peripheral blood counts, and percentages of malignant plasma cells in bone marrow samples, as well as imaging of bone lesions. Accurate assessment of response following systemic therapy is essential because of the tight relationship between the degree of response and the duration of disease control.

Classes of Therapeutic Agents

Cytotoxic Agents, Targeted Small Molecules, and Antibodies

An understanding of the pharmacologic properties and therapeutic indications of the most commonly used cytotoxic and molecularly targeted chemotherapeutic agents and antibodies approved by the FDA (see Table 164-2) is critical for prescribing physicians and is also important for physicians who participate in the patient's care. Current information should be sought from the manufacturer before therapy is initiated.

The administration of chemotherapy should be overseen by specifically trained individuals because of the dual acute risks of hypersensitivity reactions and extravasation. No doses or schedules are universally recommended because these agents are often used in combination, and the doses of each drug may need to be reduced when the compounds are combined, as well as when they are prescribed to patients who may have impaired liver or kidney function or a higher risk of adverse effects.

Unless otherwise specified, most cytotoxic chemotherapeutic agents may produce some degree of nausea and vomiting, myelosuppression, alopecia, mucositis, and/or diarrhea after treatment; many agents are also teratogenic, mutagenic, and carcinogenic. Specific drugs (see Table 164-2) often can be used to prevent agent-specific toxicities.

Small molecule anticancer agents with more precisely targeted mechanisms of action have become a standard part of oncologic practice (see Table 164-2). Although the molecular dependencies within the tumor cells against which these drugs are targeted are broad in scope, including tyrosine kinase growth factors or their receptors, they are functionally much more specific than prior generations of systemic cancer therapies. This specificity allows for a better appreciation of the clinical situations in which certain drugs might be beneficial, as well as the possibility of developing agents for use in specific tumors based on their genetic susceptibilities. The toxicity profiles of molecular targeted agents most often reflect alterations that are produced in biochemical pathways that control normal organ function, rather than a general pattern of toxicity consistent with injury to rapidly growing tissues, such as the bone marrow or gastrointestinal tract.

TABLE 164-3 PRINCIPLES OF COMBINATION THERAPY

CYTOTOXIC AGENTS	MOLECULARLY TARGETED DRUGS
Drugs are each active against the tumor	Agent has therapeutic effect on molecular pathway in vivo
Drugs have different mechanisms of action	Agents have complementary effects on the same target or other targets in the same pathway or pathways that cross-talk to control tumor growth
Drugs have different clinical toxicities to allow full doses of each to be administered	Toxicities do not overlap with cytotoxics and are moderate to low to allow prolonged administration. Consider physiologic consequences of target engagement in relation to toxicity profile
Intermittent intensive therapy is preferred to continuous treatment for cytoreduction and reducing immunosuppression	Schedule is chosen to maximize target inhibition

TABLE 164-4 COMMON EXAMPLES OF THERAPEUTIC SETTINGS

ADJUVANT THERAPY	NEOADJUVANT THERAPY	ORGAN-SPARING THERAPY	COMBINATION CHEMOTHERAPY
Stage I and II breast cancer Stage III colorectal cancer Stage II lung cancer	Stage III breast cancer	Anal cancer Laryngeal cancer Esophageal cancer	Metastatic solid tumors* Hematologic malignancies

*Usually palliative.

The development of monoclonal antibodies directed against proteins or other molecular determinants of cancer cells represents an additional approach to molecular targeting of systemic therapy. Examples include cetuximab (targeting the epidermal growth factor receptor), rituximab (targeting the B-cell CD20 surface antigen), and trastuzumab[A2] (which blocks HER2). These monoclonal antibodies can be used alone or in the form of recombinant bispecific or multispecific antibodies that provide multifunctional receptor targeting, they can be labeled with a radioactive molecule, or they can be conjugated to another cytotoxin to enhance cell killing. Radioimmunoconjugate approaches have been most effective in the treatment of non-Hodgkin lymphoma (Chapter 171) and chronic lymphocytic leukemia (Chapter 169). The effectiveness of monoclonal antibodies in specific tumor types is not identical to small molecules developed against the same target, in part because of the induction of immunologically mediated mechanisms of tumor cell killing that are unique to antibodies.

A major challenge with targeted therapy for malignancies is that drug resistance often develops. Cancers are characterized by extensive intratumor genetic heterogeneity, and resistance to molecularly targeted therapies can arise from the selected growth of preexisting subclones that are present within the bulk of the tumor and that carry drug-resistant mutations, which have a survival advantage for the tumor.[9]

Hormonal Therapies

Endocrine or hormonal therapy is almost entirely limited to breast cancer (Chapter 183) and prostate cancer (Chapter 186). Many premenopausal breast cancers are thought to be under the influence of ovarian estrogens, and hormonal deprivation (ablation) may produce long-term responses in properly selected patients (patients whose tumors express estrogen and/or progesterone receptors and who have predominantly soft tissue or bone disease). The antiestrogen tamoxifen is effective against breast cancer, and it may decrease the incidence of contralateral breast cancers in both premenopausal and postmenopausal women with breast cancer (Chapter 183). Tamoxifen also has an estrogen-like activity that is responsible for an increased rate of endometrial cancers. Postmenopausal women who are candidates for hormonal therapy may also respond to tamoxifen; however, aromatase inhibitors (e.g., anastrozole, letrozole, exemestane), which decrease the conversion of metabolites in fat and muscle into estrogen, are more effective than tamoxifen as first-line therapy in both the adjuvant and metastatic settings.

Prostate cancer (Chapter 186) is usually androgen-dependent, and androgen deprivation can produce meaningful responses. The recent introduction of more potent inhibitors of androgen biosynthesis (abiraterone) and androgen receptor-mediated signal transduction (enzalutamide) has further enhanced the range and effectiveness of androgen deprivation therapy for this disease.

The corticosteroids (Chapter 28), typically prednisone or dexamethasone, are widely used in the treatment of hematologic and oncologic cancers. In Hodgkin disease (Chapter 172), the non-Hodgkin lymphomas (Chapter 171), and multiple myeloma (Chapter 173), corticosteroids have antitumor activity. In solid tumor patients, they are used as antiemetics, for the symptomatic relief of cerebral edema in cases of CNS metastases (Chapter 175), or as an adjunct to radiation therapy for spinal cord metastases.

Epigenetic Therapies

Just as DNA mutations contribute to the progression of tumors, epigenetic alterations in the transcription of DNA also participate in the growth of tumors and their resistance to chemotherapy (Chapter 166). The two best characterized epigenetic mechanisms are DNA methylation and histone modification. DNA methylation is controlled by DNA methyltransferases, whereas histone modification (acetylation) is controlled by histone acetyltransferases. The DNA methyltransferase inhibitors (azacitidine and decitabine) produce durable responses and survival benefit in patients with myelodysplastic syndrome (Chapter 167) and acute myelogenous leukemia (Chapter 168). The histone deacetylase inhibitors (vorinostat and romidepsin) have clinical benefit for the treatment of cutaneous T-cell lymphoma (Chapter 171).

The DNA methyltransferase inhibitors also have an immune-based mechanism of action. Current clinical trials are testing the combination of epigenetic therapy plus immunotherapy in cancer treatment.[10]

Immunotherapy

Cancer immunotherapy blocks the processes by which tumors suppress the immune system. These agents have yielded dramatic clinical benefits for patients with a remarkably wide variety of advanced cancers, including melanoma, kidney, bladder, head and neck, esophageal, gastric, triple-negative breast, hepatocellular, and lung cancers, as well as Hodgkin and non-Hodgkin lymphoma. Immune checkpoint therapy targets regulatory pathways in T cells to enhance their antitumor immune responses. The goal of immune checkpoint blockade is not to activate the immune system to attack particular targets on tumor cells, but rather to remove inhibitory pathways that block effective antitumor T-cell responses. The survival of men and women with metastatic melanoma (Chapter 188) is significantly increased following treatment with antibodies (anti-CTLA-4 ipilimumab and anti-PD-1 nivolumab) that neutralize proteins that protect tumor cells against destruction by the immune system.[11] PD-1 antibodies also provide a survival benefit compared with platinum-based chemotherapy for patients with non–small cell lung cancer. Additional antibodies that target other immunologic checkpoint molecules (anti-PD-L1) provide substantive clinical benefits for patients with melanoma, renal cancer, non–small cell lung cancer, and a variety of other solid tumors and lymphomas. However, a broad range of toxicities can be associated with the use of checkpoint inhibitor therapy.[12]

Another approach to cancer immunotherapy is through adoptive cell transfer, which involves the engineering of the patient's own immune cells to recognize and attack their own tumors. In this form of treatment (CAR T-cell therapy),[13] T cells collected from a patient are genetically engineered to produce special receptors on their surface called "chimeric antigen receptors" (or "CARs"). Targeted CAR T cells have provided impressive responses in patients with B-cell malignancies and led to their FDA approval for an increasing number of indications despite a high risk of side effects, including cytokine release syndrome and acute neurologic complications.

Drugs for Prevention or Treatment of Toxicity

In addition to the hematopoietic growth factors used to reduce the adverse effects of systemic cancer therapies on the bone marrow (discussed later under Management of Complications), drugs have been developed to ameliorate important side effects of cytotoxic chemotherapy (see Table 164-2). These agents include dexrazoxane, which is an iron chelating agent that can prevent the cardiac toxicity of the anthracyclines (doxorubicin and daunorubicin); leucovorin, which can diminish the hematologic side effects of folic acid antagonists; and mesna, a thiol-containing compound that blocks damage to the bladder mucosa from metabolites of cyclophosphamide. Uridine triacetate is FDA-approved for the treatment of patients who receive an overdose of fluorouracil or capecitabine or who develop severe or life-threatening toxicities within 4 days of receiving them.

Bone Marrow or Hematopoietic Stem Cell Transplantation

Because the major dose-limiting toxicity of most chemotherapeutic agents is myelosuppression, pluripotent stem cells can be harvested from bone marrow, peripheral blood, or, less often, cord blood before marrow-damaging chemotherapy so that these stem cells can be reinfused later (Chapter 163). This technique is most effective for acute leukemias (Chapter 168), relapsed lymphomas (Chapter 171), and germ cell tumors (Chapter 185). The effectiveness of the approach is limited more by the inability to eradicate cancer cells than by the inability to achieve engraftment. Transplants may be syngeneic (from an identical twin), autologous (from oneself), allogeneic (from a matched donor such as a sibling or parent), or from a matched unrelated donor. Nonablative hematopoietic transplants that do not completely abolish myelopoiesis reduce toxicity and allow the treatment of older and medically infirm patients.

Special Treatment Populations

Obesity

Up to 40% of obese patients receive limited doses of chemotherapy that are not based on actual body weight. Concerns about toxicity or overdosing based on the use of actual body weight in obese patients with cancer are unfounded. Evidence-based practice guidelines recommend that full cytotoxic chemotherapy doses be used to treat obese patients with cancer, especially when the goal of treatment is cure.

Pregnancy

Cancer during pregnancy (Chapter 221) is not uncommon, with breast, cervical, ovarian, and thyroid cancers; melanoma; and hematologic malignancies being most frequent.[14] Cancer during pregnancy is an emotionally charged challenge, and clinical decision making is complicated by ethical, moral, cultural, and religious issues. If surgery can be safely accomplished, it may be the best course, even if it is only a temporizing measure. Radiation therapy carries the very real risk of radiation exposure to the fetus, and staging is almost always suboptimal and confined to ultrasound examinations. When the disease requires chemotherapy, both the mother and fetus must be taken into account. For example, drug clearance and gastrointestinal absorption are different during pregnancy, and placental transfer, fetal pharmacokinetics, and placental excretion can influence effective and safe drug dosing. Many commonly used chemotherapeutic drugs are classified by the FDA as category D (positive human fetal risk, but the benefits in pregnant women may be acceptable despite the risk) or category X (studies in humans and animals have shown fetal malformations or there is evidence of fetal risk based on human evidence). If the mother's condition permits, chemotherapy (including anthracyclines and taxanes) should be deferred during the first trimester and used to treat only life-threatening situations during the third trimester after extensive counseling with the parents.

The preservation of fertility is particularly challenging for women with newly diagnosed hematologic malignancies, breast cancer, sarcoma, and some pelvic cancers, for which combinations of alkylating agent chemotherapy, pelvic radiotherapy, and/or surgery are most likely to cause premature ovarian insufficiency. Options for the preservation of fertility include cryopreservation of embryos, mature oocytes, or ovarian tissue (Chapter 218).[15]

Geriatrics

An increasing proportion of cancers occur in an older population. The physiologic changes that develop with age (Chapter 23) include decreased excretion

of drugs and metabolites from the kidneys, decreased volume of distribution of water-soluble drugs, and increased susceptibility to myelosuppression, cardiomyopathy, and neuropathy, related in part to comorbid conditions (Chapter 24). As a general rule, the suitability of an older patient for therapy can be determined by a comprehensive geriatric assessment (Chapter 23) that evaluates the patient's function, comorbidity, nutrition, medications, and resources. Age itself is not a barrier to surgery; rather, the patient's performance status and the comprehensive geriatric assessment should determine the likelihood of a good recovery. Tolerance of radiation therapy seems to remain largely intact with increasing age. Chemotherapy decisions are also based on performance status and the comprehensive geriatric assessment. Dosage adjustments are also made, when appropriate, for glomerular filtration rates for patients ages 65 years and older. The use of lower chemotherapy doses based on age alone is not advisable and may result in ineffective treatment.

Organ Dysfunction

Alterations in drug clearance (Chapter 25) play a critical role in the safe administration of anticancer agents. Alterations in pharmacokinetic parameters per se may occur with or without important changes in toxicity. Where evidence exists, chemotherapeutic drug doses must be modified in the setting of renal or hepatic dysfunction (see Table 164-2).

Immunocompromised Patients

The increasing proportion of patients who survive long-term after hematopoietic cell transplantation or with hematologic malignancies are at risk of complications related to their markedly compromised immune systems. Such patients are less likely to develop protective antibodies after vaccination, are more likely to have a variety of infections (Chapter 260), and tend to become sicker with their infections. For example, patients who have hematologic malignancies have significantly lower rates of seroconversion following vaccination against SARS-CoV-2 and have higher rates of hospital admission and mortality following SARS-CoV-2 infection than do patients who have solid tumors.[16]

Management of Complications

Supportive Care

Nutritional Support

Nutrition is always a concern for patients who are newly diagnosed with cancer, even if they have not experienced weight loss. Significant weight loss is an adverse prognostic factor for several cancers, especially lung cancer.

Malnourished patients should be evaluated by a dietitian to determine whether they are ingesting sufficient calories (Chapter 198) and whether dietary supplements might be needed. Some patients, such as patients with head and neck cancers (Chapter 176) or esophageal cancers (Chapter 178), may require parenteral nutrition through a percutaneous gastrostomy tube. Total parenteral nutrition (Chapter 198) is rarely indicated.

Patients are often concerned about whether their diet contributed to development of the cancer and whether diet can influence the results of therapy. In most settings, neither of these scenarios is the case. Larger-than-recommended doses of vitamins are also not helpful and may be toxic (Chapter 199). Current or contemplated use of over-the-counter and/or alternative medications (Chapter 30) must be determined because they can have potentially important interactions with chemotherapeutic agents.

Psychosocial Support

Patients with a recent cancer diagnosis have increased risks of death from cardiovascular causes, especially during the first week after diagnosis. The associated anxiety, depression, and fear experienced by many patients commonly require substantial ongoing psychosocial support, which may exceed what the immediate family can provide. In this setting, patients often benefit from participation in support groups or from direct one-on-one counseling, as well as from efforts to improve communication across all levels of care and support systems.

Hematopoietic Growth Factors

Growth factors, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), speed the recovery of the white blood cell count, thereby often permitting chemotherapy to be given on schedule, without reducing the dosage (Chapter 142).[A3] However, such therapy does not decrease hospitalizations or improve survival. Consensus guidelines[17] can help determine which individuals are at greatest risk for febrile neutropenia (Chapter 153) and are more likely to benefit from pre-emptive treatment. Correction of anemia with erythropoiesis-stimulating agents (epoetin alfa and darbepoetin alfa) may be associated with complications of adverse cardiovascular events and even potentially tumor progression (Chapter 144).[18]

Prevention of Pathologic Bone Fractures

Bisphosphonates (e.g., pamidronate and zoledronate) are very effective not only for the treatment of tumor-induced hypercalcemia but also to reduce pathologic fractures in bones with metastatic lesions (Chapter 187), particularly from breast cancer (Chapter 183), prostate cancer (Chapter 186), and myeloma (Chapter 173). Bisphosphonates are also used to treat osteoporosis caused by chemotherapy-induced premature menopause in young women with breast cancer (Chapter 225). Denosumab (a human monoclonal antibody that binds to RANK ligand, which is a protein that is found on osteoclasts and is involved in bone breakdown) is superior to zoledronic acid for the prevention of skeletal-related events in cancer patients with bone metastases.[A4] Compared with placebo, adjuvant denosumab administered subcutaneously every 6 months reduces the risk of clinical fracture in postmenopausal women whose breast cancer is being treated with aromatase inhibitors, without any added toxicity.[A5]

Symptom Management

Effective management of symptoms is critical to successful delivery of either curative or palliative treatment and maintenance of a patient's quality of life.

Nausea and Vomiting

Patients continue to fear chemotherapy because of the risk of nausea and vomiting. Antiemetics (Table 118-5), typically used in combination,[19] have made this side effect much less debilitating. Chemotherapeutic drugs can be ranked according to their probability of causing nausea and vomiting, with prophylactic treatment given accordingly. The availability of the serotonin 5-hydroxytryptamine type 3 (5-HT_3) receptor antagonists (dolasetron, granisetron, ondansetron) has dramatically improved the ability to control nausea and vomiting completely. More emetogenic regimens require combination therapy with a corticosteroid (usually dexamethasone), a 5-HT_3 antagonist, and a benzodiazepine (e.g., lorazepam) or the neurokinin-1 receptor antagonist aprepitant. Aprepitant is particularly useful for the treatment/prevention of delayed nausea and vomiting. The combination of a neurokinin-1 receptor antagonist with dexamethasone and a 5-HT3 receptor antagonist is even better to control carboplatin-induced emesis.

Pain Control

Oncologists use a variety of scales to evaluate pain control (Chapter 26), which can be accomplished with a variety combination of analgesics, both non-narcotic and narcotic. Pharmacologic treatment should start with nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin or acetaminophen, progress through ibuprofen and related drugs (see Table 26-4), and then through combinations of NSAIDs and narcotics (see Table 26-6) to stronger narcotics.[20] Newer narcotics are available in both short-duration and long-duration forms; some dermal patches provide benefit for 72 hours and are ideal for patients who have severe pain and who are unable to take oral medications. Oral transmucosal fentanyl is more effective than standard-release morphine in this setting. Painful oral mucositis, a common complication of intensive therapy for hematologic malignancies, can be treated with local measures or with recombinant human keratinocyte growth factor (Chapter 393). Oral anti-*Candida* drugs that are absorbed or partially absorbed from the gastrointestinal tract can help prevent pain from oral candidiasis (Chapter 310); both pharmacologic and psychosocial interventions (e.g., relaxation training, cognitive-behavioral therapy, and other education- and skills-based approaches) are complementary approaches that have real but relatively modest effects on both the severity of pain and its interference with daily activities.

Malignant Effusions

Accumulations of fluid and malignant cells in the pleural (Chapter 86), peritoneal, or pericardial spaces (Chapter 62) are common complications of epithelial and hematopoietic malignancies that frequently produce a significant array of symptoms, either at the time of diagnosis or accompanying tumor progression. Malignant pleural effusions (Chapter 86) are most commonly associated with cancers of the lung and breast or lymphomas, may be the result of lymphatic obstruction or direct invasion of pleural membranes, and can produce significant degrees of dyspnea, cough, or pain that require therapy. Diagnostic thoracentesis of sufficient volume (>60 mL), with cytologic analysis of the pleural effusion, has a reasonably high diagnostic yield for malignancy (60 to 90%). In patients with previously untreated lymphoma, breast cancer, or small cell lung cancer, objective response to the initiation of systemic chemotherapy may provide long-term symptomatic relief. However, in patients with recurrent lung or breast cancer, for example, pleural effusions that are confirmed to contain malignant cells may present difficult ongoing therapeutic challenges. For symptomatic patients, therapeutic thoracentesis, usually under ultrasound guidance, is required and may need to be repeated to reduce dyspnea. When frequent thoracenteses over short intervals are needed, drainage of the pleural space is combined with a chest thoracostomy and the instillation of a sclerosing compound (talc, doxycycline) that will initiate an inflammatory response of sufficient magnitude to obliterate the pleural space (Chapter 86). Such pleurodesis is usually at least temporarily successful in preventing fluid recurrence in most patients. When it is no longer successful, placement of an indwelling pleural catheter may provide long-term symptomatic relief of dyspnea.

Malignant ascites (peritoneal effusion) occurs most frequently in patients with intra-abdominal malignancies (gastric, ovarian, pancreatic, and primary peritoneal cancers) but also can be observed in patients with advanced breast and lung cancers or lymphoma. Malignant ascites may be caused in part by increased permeability of the tumor vasculature as a result of overexpression of vascular endothelial growth factor, by the overproduction of inflammatory cytokines in the peritoneal space, or by lymphatic blockade secondary to carcinomatosis. Ultrasound-guided paracentesis provides relief of bloating, dyspnea, and the pain of abdominal distension. However, paracentesis must be repeated,

with an associated risk of dehydration, loss of protein, electrolyte imbalance, bleeding, infection, and kidney dysfunction. If paracentesis is required more often than once per week, prompt placement of a permanent catheter should be considered to allow self-drainage, even though these devices carry a significant risk of infection.

Malignant pericardial effusions (Chapter 62) are most commonly related to direct extension or metastatic spread from lung or breast cancers, melanomas, and hematologic malignancies. As is the case for other malignant effusions, image-guided pericardiocentesis with cytologic examination of the fluid that has been evacuated will frequently provide diagnostic confirmation of malignancy. Furthermore, the removal of even a relatively modest amount of fluid (<50 mL) may, at least partially, relieve the hemodynamic compromise produced by the effusion. The approach to a patient with malignant pericardial effusions is dictated by hemodynamic status (which can drive the choice between emergency pericardiocentesis or elective pericardiostomy) and by the predicted sensitivity of the inciting tumor to systemic therapy (e.g., untreated lymphoma versus chemotherapy-resistant lung cancer).

ENDOCRINE MANIFESTATIONS OF CANCER

Clinical syndromes associated with ectopic hormone production may pose special diagnostic dilemmas, can produce a significant degree of morbidity or even death in cancer patients, and may be difficult to treat (Table 164-5). Management of these syndromes involves the simultaneous treatment of both the cancer and the syndrome caused by excessive hormone production. Many of the endocrine manifestations of cancer[21] are caused by the production of small polypeptide hormones by tumors, some of which are derived from specific types of neuroendocrine cells. These cells are widely dispersed in a wide variety of organs, are often of neural crest origin, and can produce biogenic amines. The hormones produced from these tumors include adrenocorticotropic hormones (corticotropin, ACTH), calcitonin, vasoactive intestinal peptide, growth hormone–releasing hormone, corticotropin-releasing hormone (CRH), somatostatin, and other peptides. A second group of tumors, generally derived from squamous epithelium, produces parathyroid hormone–related proteins (PTHrP) and vasopressin.

TABLE 164-5 SOME CLINICAL SYNDROMES OF ECTOPIC HORMONE PRODUCTION

Humoral hypercalcemia
Parathyroid hormone–related protein
Squamous cell carcinoma
Breast cancer
Neuroendocrine tumors
Renal cell cancer
Melanoma
Prostate cancer
Increased calcitriol
Lymphoma
Benign conditions: sarcoid, berylliosis, tuberculosis, fungal infections
Corticotropin
Proopiomelanocortin
Small cell lung cancer
Pulmonary carcinoid
Medullary thyroid cancer
Islet cell tumor
Pheochromocytoma
Ganglioneuroma
Corticotropin-releasing hormone
Medullary thyroid cancer
Paraganglioma
Prostate cancer
Islet cell tumors
Human chorionic gonadotropin
Choriocarcinoma
Testicular embryonal cell carcinoma
Seminoma
Hypoglycemia
Insulinoma
Sarcomas or large retroperitoneal tumors
Inappropriate antidiuretic hormone secretion
Small cell lung cancer
Squamous cell head and neck cancer
Erythropoietin
Renal cell cancer
Hepatocellular carcinoma
Pheochromocytoma
Benign conditions: cerebellar hemangioblastoma, uterine fibroids

HYPERCALCEMIA OF MALIGNANCY

Humoral hypercalcemia (Chapter 227) is one of the most common endocrine syndromes related to an underlying malignancy. One of the most common causes of hypercalcemia of malignancy[22] is the ectopic production of parathyroid hormone–related protein, with resulting activation of the PTH receptor, an increase in the differentiation of osteoclasts, and increased bone resorption and consequent hypercalcemia. Ectopic parathyroid hormone–related protein (rather than PTH itself) can be produced by several different types of cancer, most characteristically squamous cell cancer, breast cancer, renal cell cancer, and prostate cancer, as well as by neuroendocrine tumors and melanoma (see Table 164-5). Increased production of calcitriol, which increases the absorption of calcium and suppresses levels of serum PTH, is another cause of malignant hypercalcemia, most commonly in patients with lymphoma. Bone metastases (Chapter 187), particularly in patients with breast cancer and myeloma, may produce hypercalcemia due to increased local production of PTHrP or other cytokines that increase bone resorption.

TREATMENT

The treatment of malignant hypercalcemia is similar to hypercalcemia that is caused by hyperparathyroidism (Chapter 227). The reversal of dehydration and the initiation of a saline diuresis should begin promptly; patients with a serum calcium in excess of 13 mg/dL should be treated with a bisphosphonate initially, with extended use of the bisphosphonate for the prevention of bone fractures and recurrence of hypercalcemia (Chapter 227).

OTHER ECTOPIC HORMONE SYNDROMES

Inappropriate secretion of ACTH is rare but resembles pituitary Cushing disease (Chapter 208). Tumors that produce corticotropin-releasing hormone include medullary thyroid cancer, prostate cancer, and islet cell neoplasms. Ectopic ACTH syndrome may manifest as classic Cushing syndrome, with easy bruisability, centripetal obesity, muscle wasting, hypertension, diabetes, and metabolic alkalosis. However, many patients with ectopic ACTH-producing cancers progress too quickly to develop prominent cushingoid manifestations clinically. Profound hypokalemia may predominate without the classic features of Cushing syndrome in patients with small cell lung cancer (Chapter 177).

Tumor-associated hypoglycemia (Chapter 211), although uncommon, may be the result of the overproduction of insulin by islet cell tumors; insufficient hepatic gluconeogenesis related to loss of functional hepatic mass by metastatic disease; or overexpression of insulin-like growth factor II, which can activate the insulin receptor in patients who have large retroperitoneal sarcomas or hepatocellular carcinomas. In each of these cases, treatment with frequent small feedings can be prescribed; however, successful symptomatic management of hypoglycemia may be difficult without control of the primary tumor mass or metastases.

The clinical syndrome of inappropriate secretion of antidiuretic hormone (Chapter 102) is caused by ectopic production of vasopressin, primarily in patients who have small cell lung cancer (Chapter 177) or squamous cancers of the head and neck (Chapter 176), and occasionally in patients with primary brain tumors (Chapter 175). This syndrome is characterized by hyponatremia, hypo-osmolality, excessive urine sodium excretion, and an inappropriately high urine osmolality for the low serum osmolality despite normal kidney, adrenal, and thyroid function. The hyponatremia in this condition is euvolemic. Fluid (free water) restriction can provide adequate short-term management of symptomatic hyponatremia, but treatment with demeclocycline, which blocks the effects of vasopressin on the kidney, provides more effective long-term therapy (Chapter 102).

PARANEOPLASTIC SYNDROMES

The term *paraneoplasia*, which means "alongside cancer," has been commonly used to denote a cancer's remote effects that cannot be attributed either to direct invasion or to distant metastases. These syndromes (Table 164-6)[23] affect up to 15% of patients with cancer; if patients with cachexia are excluded, however, the incidence probably drops to only a few percent.

Up to two thirds of paraneoplastic syndromes arise before an associated malignancy is diagnosed. In some cases, the paraneoplastic syndrome may be associated with relatively small tumors, and recognition of these associations may lead to earlier diagnosis and possibly more effective therapy. Furthermore, one of the hallmarks in defining a paraneoplastic syndrome is that the course of the syndrome generally parallels the course of the tumor. As a result, effective treatment of the underlying malignancy is often accompanied by improvement or resolution of the syndrome. Conversely, recurrence of the cancer may be heralded by the return of systemic symptoms.

TABLE 164-6 EVALUATION AND DIAGNOSIS OF PARANEOPLASTIC SYNDROMES

- Characterize abnormality; obtain laboratory studies and biopsy as necessary
- Carefully elicit any additional symptoms and signs
- Eliminate common causes
- If there is no obvious etiology, consider a paraneoplastic syndrome
- If findings are consistent with a known syndrome, screen for underlying malignancy
- If signs and symptoms are consistent with a known paraneoplastic syndrome, undertake a search for an unknown primary cancer or recurrence or progression of a known primary tumor
- Screening should include a careful physical examination including breast, gynecologic, and prostate evaluations; basic hematology, chemistry, and urine studies; chest radiograph; and mammogram
- Computed tomography (CT) of the abdomen and pelvis or positron emission tomography (PET) scan is indicated if there are any suspicious symptoms, signs, or laboratory abnormalities of cancer
- Antibody testing for paraneoplastic neurologic syndromes and/or skin biopsy should be performed as indicated
- Consider treatment of cancer and/or appropriate palliative treatment, including immunosuppressive therapy for paraneoplastic symptoms when possible

NEUROLOGIC PARANEOPLASTIC SYNDROMES

A variety of neurologic paraneoplastic syndromes[24] can complicate many different cancers, with small cell lung cancer (Chapter 177) being an especially common cause (Table 164-7). Lambert-Eaton myasthenic syndrome (Chapter 390) mimics myasthenia gravis clinically, with the exception that strength improves rather than deteriorates with sustained voluntary contraction. Paraneoplastic encephalitis, subacute sensory neuropathies (Chapter 388), and sensory ganglionopathies are also commonly associated with small cell lung cancer. Symptoms often include asymmetric numbness and paresthesias, as well as posterior column signs of loss of proprioception and vibratory sensation. Paraneoplastic cerebellar degeneration may be acute-onset and can mimic a cerebellar tumor (Chapter 175). Plasma cell dyscrasia and some lymphoproliferative neoplasms are associated with demyelinating peripheral neuropathies and with motor neuron symptoms that may mimic amyotrophic lateral sclerosis (Chapter 387). Polymyositis and dermatomyositis (Chapter 248) can be associated with a variety of tumors.

Paraneoplastic neurologic syndromes are more common with advanced tumors and are uncommonly the initial presenting manifestation, except perhaps with small cell cancers of the lung, plasma cell dyscrasias, and other

TABLE 164-7 PARANEOPLASTIC NEUROLOGIC SYNDROMES

NEUROLOGIC SYNDROME	CLINICAL MANIFESTATIONS	DIAGNOSIS	ANTIBODY AND ASSOCIATED MALIGNANCY
Lambert-Eaton myasthenic syndrome (Chapter 390)	Proximal lower limb weakness, with improvement in strength after several seconds of sustained voluntary contraction	Electromyogram showing *increased* muscle action potential with repeated nerve stimulation >10 Hz (opposite of myasthenia gravis)	Anti-VGCC or anti-SOX1 in small cell lung cancer (>80%)
Paraneoplastic encephalomyelitis/subacute sensory neuropathy (Chapter 383)	Subacute patchy or asymmetrical numbness, burning or aching paresthesias, and sensory ataxia with loss of proprioception and vibration sense	Clinical diagnosis supported by circulating antibodies and elevated cerebrospinal fluid protein levels with a lymphocytosis	Usually anti-Hu in small cell lung cancer; others include anti-SOX1 and anti-amphiphysin (small cell lung cancer, neuroblastoma), anti-Ma (small cell lung cancer, breast cancer), and anti-Trk (various carcinomas and lymphomas)
Paraneoplastic cerebellar degeneration	Often abrupt onset of dysarthria, ataxia, and oculomotor dysfunction	Clinical diagnosis supported by the presence of circulating antibodies, which also can be found in patients who have a variety of cerebellar disorders but no evidence of cancer; cerebrospinal fluid pleocytosis and elevated protein levels	Anti-Yo, anti-SOX1, or anti-Ri (breast, ovarian, and other gynecologic malignancies); anti-Hu (breast cancer); anti-Tr and anti-GluR (small cell lung cancer); and anti-Ma (Hodgkin lymphoma, various carcinomas)
Limbic encephalopathy (Chapter 383)	Subacute amnestic syndrome, affective disorder, seizures	Improvement common with treatment of underlying tumor	Anti-Hu, anti-amphiphysin, anti-SOX1, anti-VGKC, and anti-AMPA (small cell lung cancer); anti-Ta (testicular and breast cancers)
Stiff-person syndrome (Chapter 380)	Progressive muscle stiffness and rigidity, with intermittent and painful muscle spasms	Electromyogram showing continuous firing of motor unit potentials; may respond to muscle relaxants and improve with cancer therapy	Anti-amphiphysin (breast and small cell lung cancers) and anti-GAD (breast cancer)
Neuromyotonia (Chapter 390)	Diffuse muscle stiffness and cramps	Responds to treatment of tumor and immunosuppression	Anti-VGCC (thymoma)
Demyelinating neuropathies (including chronic demyelinating polyneuropathy, mononeuritis multiplex; Chapter 388)	Sensory more common than motor	IgM paraprotein may cross-react with myelin-associated glycoprotein, cryoglobulins	Plasma cell and lymphoproliferative neoplasms, osteosclerotic myeloma, POEMS, small cell lung cancer, other carcinomas
Necrotizing myelopathy	Symptoms associated with specific levels of spinal cord dysfunction; rapid deterioration and death		Variety of carcinomas and lymphomas
Motor neuron disease (Chapter 387)	Similar to amyotrophic lateral sclerosis with progressive weakness	Paraproteinemia	Plasma cell and lymphoproliferative neoplasms
Polymyositis/dermatomyositis (Chapter 248)	Proximal muscle weakness, skin lesions (Chapter 248)	May improve with treatment of cancer	Variety of carcinomas

AMPA = α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; GAD = glutamic acid decarboxylase; GluR = glutamate receptor; IgM = immunoglobulin M; POEMS = polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes associated with osteosclerotic myeloma; VGCC = voltage-gated calcium channel; VGKC = voltage-gated potassium channel.

lymphoproliferative diseases. Paraneoplastic neurologic syndromes may show some response to effective treatment of the tumor, but they can also progress despite such therapy.

DERMATOLOGIC PARANEOPLASTIC SYNDROMES

Associations between cutaneous syndromes and underlying malignancies may be difficult to confirm. Generally, the skin condition and cancer follow a parallel course, and the two diagnoses should be made at about the same time. Some skin lesions are almost always associated with malignancy. Others, however, are nonspecific and are most commonly seen with nonmalignant conditions, thereby making it difficult or impossible to connect the skin disease with the underlying malignancy. In addition, biopsies of the skin lesion are usually nonspecific and show features identical to what are seen when the same lesion occurs without a malignant condition. The formation of tumor-related autoantibodies has rarely been associated with dermatologic paraneoplastic syndromes, although inflammatory cell infiltration may be seen.

Recognition of cutaneous manifestations of malignancy can be critical for the early diagnosis and successful treatment of cancer,[25] but some syndromes are seen only with advanced, incurable disease. Cutaneous manifestations include direct involvement of the skin with tumor as well as the remote effects of cancer. Both specific and nonspecific dermatologic adverse effects are also seen with cytotoxic chemotherapeutic agents, including alkylating agents, antimetabolites, anthracyclines, tyrosine kinase inhibitors, and immunotherapies.

One of the best-known paraneoplastic syndromes is acanthosis nigricans (Chapter 408 and Fig. 408-14), the pathogenesis of which is unclear. The tumor may produce factors that activate insulin-like growth factors or the insulin receptor in skin. Many tumors are known to produce transforming growth factor-α (TGF-α), which might activate epidermal growth factor receptors in the skin, causing hyperpigmentation and thickening. The skin lesions arise as velvety, verrucous hyperpigmentation of the neck, axilla, groin, and mucosal membranes, including the lips, periocular area, and anus. Although acanthosis nigricans clearly occurs as a benign entity associated with obesity and endocrinopathy, its appearance in older adults, especially when it includes mucosal lesions, is highly associated with malignancies of the gastrointestinal tract as well as with other adenocarcinomas. The lesions often regress with successful treatment of the underlying tumor.

RHEUMATOLOGIC PARANEOPLASTIC SYNDROMES

The possibility of an underlying occult malignancy should be considered[26] in patients who have rheumatic disorders with an atypical clinical presentation, particularly older patients, patients who have coexisting systemic symptoms, and patients who respond unexpectedly poorly to usual antirheumatic treatments. Chemotherapeutic agents can also cause rheumatic adverse effects.

One of the more common and specific rheumatologic paraneoplastic syndromes is hypertrophic osteoarthropathy,[27] which arises as an oligoarthritis or polyarthritis of the distal joints, with clubbing (Fig. 39-9), tender periostitis of the distal long bones, and noninflammatory synovial effusions (also see Chapter 254). Hypertrophic osteoarthropathy may affect up to 10% of patients with adenocarcinoma of the lung and is also seen with a variety of other pulmonary malignancies, including lung metastases from other primary sites. The etiology is unknown. Laboratory studies often reveal an elevation in the erythrocyte sedimentation rate; bone radiographs show linear ossification of the distal long bones separated by a radiolucent zone from the underlying cortex (Fig. 164-1).

TREATMENT

Treatment is symptomatic with anti-inflammatory agents. Successful treatment of the underlying tumor may also improve the signs and symptoms of this syndrome.

RENAL AND HEPATIC PARANEOPLASTIC SYNDROMES

The most common renal paraneoplastic syndrome is membranous glomerulonephritis, which can include nephrotic-range proteinuria, edema, hypertension, hypoalbuminemia, and microscopic hematuria (Chapter 100). The most common associated cancers include adenocarcinoma of the lung (Chapter 177), breast cancers (Chapter 183), and gastric adenocarcinomas (Chapter 178). Lymphoproliferative disorders, especially Hodgkin disease (Chapter 172), can cause minimal-change nephropathy. Renal microangiopathy can be seen with cryoglobulinemia associated with hepatitis C–related hepatocellular carcinoma (Chapter 181). Paraneoplastic hepatopathy with elevated liver enzymes and abnormal synthetic function can be seen with renal cell cancer (Chapter 182) without evidence of direct hepatic involvement by the tumor.

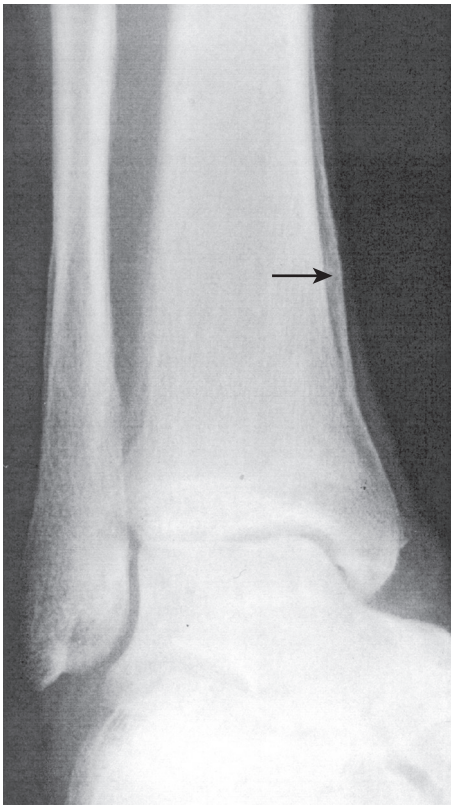

FIGURE 164-1. Hypertrophic pulmonary osteoarthropathy characterized by periosteal elevation of the tibia (*arrow*). (Courtesy Dr. Lynne S. Steinbach.)

HEMATOLOGIC PARANEOPLASTIC SYNDROMES

The most common immunologic paraneoplastic syndrome is thrombosis (Chapters 67 and 68). Some patients have hemorrhagic paraneoplastic syndromes, especially disseminated intravascular coagulation (Chapter 161), that can be seen in nearly all patients with acute promyelocytic leukemia (Chapter 168). Acquired von Willebrand disease (Chapter 159) may be seen in rare cases of lymphoproliferative and myeloproliferative disorders, and increased fibrinolysis can occur in patients with advanced prostate cancer (Chapter 186).

Anemia of chronic disease (Chapter 144) is a common finding in cancers of all types. Pure red cell aplasia (Chapter 151) is a rare condition associated with benign or malignant thymomas (Chapters 86 and 390).

Paraneoplastic hemolytic anemia (Chapter 147) can be seen with warm- or cold-reacting antibodies, especially in patients with chronic lymphocytic leukemia (Chapter 169). Microangiopathic hemolytic anemia (Chapter 147) with thrombocytopenia is a common complication of a variety of adenocarcinomas. Erythrocytosis is seen in tumors that produce erythropoietin, including renal cell cancers (Chapter 182), hepatocellular carcinomas (Chapter 181), and cerebellar hemangioblastomas (Chapter 175).

Patients with advanced cancer can develop leukocytosis caused by cytokines in the absence of infection. Eosinophilia (Chapter 156) can be seen with lymphoproliferative diseases, including Hodgkin disease. Paraneoplastic thrombocytosis (Chapter 152) is caused by tumors that produce interleukin-6 or thrombopoietin.

FEVER AND CACHEXIA

Fever (Chapter 260), night sweats, and cachexia are nonspecific symptoms that, when seen in the absence of infection or a known disorder, suggest the diagnosis of an underlying malignancy. Cytokines clearly play a pathogenetic role in inducing both fever and cachexia. TNF-α, interleukins (particularly IL-1 and IL-6), and interferon-γ, which result in a catabolic state, are produced directly by the tumor or by tumor-associated host inflammatory cells, such as macrophages. Cytokines may produce fever directly by acting at the level

of the hypothalamic thermoregulatory center. In addition to the burden of tumor and the production of cytokines, cachexia may be caused or worsened by the side effects of cancer treatment, by intestinal blockage or malabsorption caused by tumor infiltration, and by depression.

Fever is generally cyclic and may be associated with drenching night sweats. Symptoms resolve with successful treatment of the underlying tumor, and return of fever usually heralds relapse. When treatment of the tumor is not possible or is ineffective, NSAIDs (see Table 26-4) or corticosteroids given around the clock significantly improve quality of life. Although cancer-related fever is most commonly seen in association with malignant lymphoproliferative disease (Chapters 171 and 172), renal cell carcinoma (Chapter 182), and leukemias (Chapters 168 to 170), it may also occur with other cancers, particularly in the face of extensive hepatic metastases.

Cachexia, or cancer wasting syndrome, is probably the single most common paraneoplastic syndrome and eventually affects up to 80% of patients with cancer. Cachexia appears to be caused by a combination of protein wasting, malabsorption, immune dysregulation, and increased glucose turnover in the setting of tumor-induced increases in energy expenditure. This syndrome is characterized by anorexia, muscle wasting, loss of subcutaneous fat, and fatigue.

TREATMENT

Successful treatment of the underlying tumor reverses the process. By comparison symptomatic treatment for patients with advanced disease is modestly successful at best. Megestrol acetate given in high concentrations in liquid form (400 to 800 mg/day) can improve appetite and result in weight gain, but at the cost of fluid retention. Anamorelin, which is an oral ghrelin-receptor agonist with appetite-enhancing and anabolic activity (100 mg orally once daily), provides a favorable clinical response, including a significant increase in lean body mass.[A6,A7]

TUMOR LYSIS SYNDROME

Tumor lysis syndrome can be a major complication of the rapid response of hematologic malignancies and occasionally solid tumors to successful chemotherapy.[28] The sudden release of cellular contents (especially potassium, phosphate, and nucleic acids) can lead to deposition of uric acid and calcium phosphate in renal tubules. Clinical manifestations can include renal failure, seizures, and cardiac arrhythmias. Laboratory findings include elevated serum levels of uric acid, potassium, and phosphorus, with a decreased calcium level.

TREATMENT AND PROGNOSIS

The risks of complications from tumor lysis syndrome can be reduced by vigorous hydration and the prophylactic administration of allopurinol (300 mg daily), started at least 24 hours before chemotherapy and continued until uric acid levels normalize (Chapter 252). Another option is the therapeutic use of rasburicase (0.15 mg/kg intravenously, usually once, but it can be given daily for up to 5 days if needed).[29]

CANCER OF UNKNOWN PRIMARY ORIGIN

Some cancers present with biopsy-confirmed visceral or nodal metastases in the absence of an obvious primary lesion. Subsequent clinical evaluation, with a comprehensive history, physical examination, complete blood cell count, screening chemistries, chest and abdominal CT scans, and other radiologic studies directed by specific symptoms or signs can often identify the primary tumor site and clarify the extent of metastatic disease. When a primary tumor cannot be located despite such a clinical evaluation, the patient is classified as having *cancer of unknown primary origin*. Additional clinical, pathologic, and genetic evaluation can sometimes identify the primary site, but in up to 90% of patients a primary site may never be identified throughout their subsequent clinical course.

In patients whose primary cancer site remains undetectable, the primary site has presumably remained small or, less likely, regressed spontaneously. Approximately 4% of all cancer patients have metastatic disease without a known primary site, and autopsies identify a primary site in only about 50% to 70% of these patients. Cancer of unknown primary site increases with advancing age, but it occurs with about equal frequency in men and women.

DIAGNOSIS

The initial clinical, radiographic, and pathologic evaluations should focus not only on identifying a primary site but also on trying to identify tumors for which specific treatments may be most beneficial.

Biopsy and Pathologic Evaluation

The diagnosis of metastatic cancer should first be confirmed by biopsy of the most easily accessible lesion. A fine-needle aspiration is often adequate to confirm the diagnosis of cancer, but it will not provide adequate material for optimum pathologic evaluation. A larger surgical or core needle biopsy should be performed if technically feasible.

In about 60% of patients with cancer of unknown primary site, the initial microscopy will identify an adenocarcinoma. Other common light microscopy findings include poorly differentiated carcinoma (25%), squamous cell carcinoma (10%), and poorly differentiated neoplasm (inability to distinguish among carcinoma, lymphoma, sarcoma, and melanoma; 5%).

For poorly differentiated tumors, additional pathologic evaluation is required. An immunohistochemical stain usually can determine the lineage (e.g., carcinoma vs. lymphoma vs. sarcoma) of a "poorly differentiated neoplasm," and it sometimes can identify germ cell tumors or neuroendocrine carcinoma. More than 50% of such patients will have a lymphoma, for which treatment can be highly effective.

In patients with adenocarcinoma, immunohistochemical stains can narrow the diagnostic spectrum, particularly when interpreted in conjunction with clinical features. In several situations, immunohistochemical stains are quite specific, including prostate-specific antigen (PSA) for prostate cancer (Chapter 186), estrogen and progesterone receptors for breast cancer (Chapter 183), and leukocyte common antigen for non-Hodgkin lymphoma (Chapter 171). Other diagnoses suggested by immunoperoxidase staining include melanomas (Chapter 188), sarcomas (Chapter 187), and neuroendocrine tumors. Occasionally, electron microscopy or analysis for tumor-specific chromosomal abnormalities (i12p in germ cell tumors, Chapter 185; t11 : 22 in Ewing tumor; immunoglobulin gene rearrangements in non-Hodgkin lymphoma, Chapter 171) are useful in the evaluation of poorly differentiated tumors if results of other pathologic studies are inconclusive.

Since cancers usually retain gene expression profiles that are similar or even identical to their tissue of origin, modern molecular profiling can correctly predict the origin of more than 90% of metastatic cancers by finding such tissue-specific gene expression patterns.[30] Although the accuracy of genetic profiling is uncertain in patients with cancer of unknown primary origin, in part because most primaries never become manifest, current data suggest a similarly high accuracy rate. As a result, molecular tumor profiling is now a routine complement to pathologic evaluation and is indicated whenever a tissue of origin is not definitive on histologic examination.

Search for the Primary Site

After completion of the brief and focused evaluation needed to make the initial diagnosis of cancer of unknown primary origin, any additional diagnostic studies should be carefully targeted (Table 164-8). The value of positron emission tomography (PET) in identifying a primary site is unclear because it has not been shown to provide increased information above and beyond CT scanning.[31] Other routine radiologic and endoscopic evaluations of asymptomatic areas are rarely helpful for identifying a primary site and, as a result, are not recommended. Levels of serum tumor markers, including carcinoembryonic antigen, CA-125, CA-19-9, and CA-15-3, are frequently elevated in patients with carcinoma of unknown primary site, but such elevations are nonspecific and are not useful for inferring a primary site. They can, however, be useful to monitor a patient's response to treatment.

Specific clinical findings warrant additional diagnostic evaluation. In all men with metastatic adenocarcinoma, a serum PSA level should be measured. Mammography and breast MRI are routine components of the evaluation of women with metastatic adenocarcinoma, particularly if clinical features are consistent with metastatic breast cancer (e.g., axillary node involvement, pleural effusion, lytic or blastic bone metastases). In patients who are younger than age 50 years and who have poorly differentiated carcinoma, serum human chorionic gonadotropin and α-fetoprotein (AFP) levels are indicated to screen for germ cell tumors. If metastatic squamous carcinoma involves cervical lymph nodes, a thorough endoscopic head and neck evaluation, from the nasopharynx to the larynx, and biopsy of any suspicious areas are indicated (Chapter 176). In patients who have low cervical adenopathy but no identifiable primary site in the head or neck on endoscopic examination, fiberoptic bronchoscopy should also be considered. In patients with metastatic squamous carcinoma involving inguinal lymph nodes, all perineal structures should be carefully inspected, including by anoscopy, a urologic evaluation, and a pelvic examination in women.

TABLE 164-8 CANCER OF UNKNOWN PRIMARY ORIGIN: RECOMMENDED EVALUATION AFTER INITIAL LIGHT MICROSCOPIC DIAGNOSIS

DIAGNOSIS	CLINICAL EVALUATION*	SPECIAL PATHOLOGIC STUDIES
Adenocarcinoma (or poorly differentiated adenocarcinoma)	PET CT of the chest and abdomen Men: serum PSA Women: mammography, breast MRI Colonoscopy (patients with colon cancer "profile") Additional directed radiologic or endoscopic studies to evaluate abnormal symptoms, signs, laboratory values	Men: PSA stain Women: estrogen and progesterone receptor stains (if clinical features suggest metastatic breast cancer) Molecular tumor profiling
Poorly differentiated carcinoma	PET CT of the chest and abdomen Serum hCG and AFP Additional directed radiologic or endoscopic studies to evaluate abnormal symptoms, signs, and laboratory values	Immunoperoxidase staining Molecular tumor profiling Electron microscopy (if other studies are indeterminate or conflicting)
SCC, cervical nodes	PET Direct laryngoscopy with visualization; biopsy of the nasopharynx, pharynx, hypopharynx, and larynx Fiberoptic bronchoscopy (if laryngoscopy results are negative)	—
SCC, inguinal nodes	PET Complete examination of perineal area (including pelvic examination) Anoscopy Cystoscopy	—

*In addition to a history, physical examination, complete blood cell counts, chemistry profile, and chest radiograph.

AFP = α-fetoprotein; CT = computed tomography; hCG = human chorionic gonadotropin; MRI = magnetic resonance imaging; PET = positron emission tomography; PSA = prostate-specific antigen; SCC = squamous cell carcinoma.

From Hainsworth J, Greco FA. Approach to the patient with cancer. In: Goldman L, Schafer AI, eds. *Cecil Medicine,* 25th ed. Philadelphia: Elsevier; 2015.

TREATMENT AND PROGNOSIS

Site-Specific Therapy Directed by Molecular Tumor Profiling

Site-specific treatment of metastatic tumors, as characterized by their molecular profiling,[32] is the standard treatment (Table 164-9), and empiric chemotherapy should be reserved for the minority of patients whose tumors cannot be classified by molecular profiling. In general, the response to treatment and subsequent survival are consistent with the predicted types of cancer, and median survival is at least twice as long for patients who have more responsive tumors. Targeted treatment results in a median survival of 12.5 months, but some patients remain progression-free for more than 5 years.[A8]

Adenocarcinoma

Women with Axillary Lymph Node Metastases

Metastatic breast cancer should be suspected in any woman who has axillary lymph node involvement with adenocarcinoma, particularly if an alternative metastatic site is not evident. In these patients, pathologic evaluation of the initial lymph node biopsy should include staining for estrogen and progesterone receptors and for *HER-2* expression; elevated levels strongly suggest the diagnosis of breast cancer.

When no other metastases are identified, these women should be treated as if they had stage II breast cancer, which is potentially curable with appropriate therapy (Chapter 183). Modified radical mastectomy identifies a breast primary site in about 45 to 80% of women, even when the breast examination and mammographic findings are normal. Axillary lymph node dissection followed by radiation therapy to the breast appears to give results similar to those of mastectomy, although these two options for primary therapy have not been compared directly. Adjuvant systemic therapy should follow standard guidelines for treating women with stage II breast cancer.

Women with Peritoneal Carcinomatosis

Adenocarcinoma involving the peritoneum in women usually originates from the ovary (Chapter 184), although carcinomas arising in the gastrointestinal tract or breast can occasionally produce this syndrome. Diffuse peritoneal carcinomatosis can occasionally occur in women who have histologically normal ovaries or who have had previous bilateral oophorectomy. The peritoneum is frequently the only site of tumor involvement, and serum CA-125 levels are usually elevated. When histologic features suggest ovarian cancer, this syndrome has been called *peritoneal papillary serous carcinoma* or *primary extraovarian serous carcinoma*.

Even when the histologic features are not typical, women with adenocarcinoma of unknown primary site involving the peritoneum often have cancers that are biologically similar to ovarian cancer (Chapter 184). In such patients, treatment should follow guidelines for stage III ovarian cancer. A full laparotomy with maximal surgical cytoreduction should be performed when feasible, and it should be followed by combination chemotherapy with a taxane/platinum-containing regimen. Serial measurement of serum CA-125 levels can accurately assess the efficacy of treatment. Some patients may have complete responses and long-term survival, particularly when initial surgical cytoreduction leaves minimal residual disease. A similar syndrome of peritoneal carcinomatosis that is responsive to chemotherapy for ovarian cancer has rarely been reported in men.

Men with Skeletal Metastases or Elevated Serum Prostate-Specific Antigen Levels

Metastatic prostate cancer (Chapter 186) should be suspected in men who have an adenocarcinoma that predominantly involves bone, particularly if the metastases are blastic. An elevated serum PSA level or PSA tumor immunostaining confirms the diagnosis of prostate cancer. Occasionally, men who have adenocarcinoma of unknown primary site and metastatic patterns that are unusual for prostate cancer (e.g., lung metastases, mediastinal lymph node metastases) nevertheless have elevated serum PSA levels. Such patients should be treated according to guidelines for advanced prostate cancer. Androgen ablation produces excellent responses and substantial palliation in most patients.

Single Metastatic Lesion

Occasionally, a single metastatic lesion containing adenocarcinoma or poorly differentiated carcinoma is identified, and a complete evaluation reveals absolutely no other evidence of disease. Such single lesions may be a single lymph node, a subcutaneous site, or visceral lesions in liver, lung, bone, brain, or adrenal gland. One possibility is that an unusual primary tumor is mimicking a metastatic lesion (e.g., a subcutaneous nodule from a primary apocrine or sebaceous carcinoma rather than a metastasis). This possibility can usually be excluded on clinical or pathologic grounds, and PET scanning is useful to exclude other metastatic lesions.

In patients who have only a single identifiable lesion, definitive local therapy is recommended. Based on the site of the tumor, such therapy may include surgical resection, radiation therapy, or both. Although most such patients eventually have other evidence of metastatic disease, local treatment can provide substantial palliation, and some patients experience a significant disease-free period. The role of adding systemic chemotherapy to definitive local therapy is uncertain, but younger patients who have poorly differentiated carcinoma or adenocarcinoma are often treated with a short course of a taxane/platinum-based regimen.

Colon Cancer Profile

In a patient who has cancer of unknown primary origin, a colon cancer profile includes metastases seen predominantly in the liver, peritoneum, or both; an adenocarcinoma that has histologic features typical of gastrointestinal origin; and typical immunohistochemical staining (CK20 positive, CK7 negative, and CDX-2 positive). Patients who have such a profile should be treated according to guidelines for metastatic colorectal cancer (Chapter 179).

TABLE 164-9 CANCER OF UNKNOWN PRIMARY ORIGIN: SPECIFIC PATIENT SUBSETS AND RECOMMENDED TREATMENT

SUBSET-IDENTIFYING FEATURES		
HISTOLOGIC	**CLINICAL**	**TREATMENT RECOMMENDATIONS**
Adenocarcinoma	Women, isolated axillary adenopathy	Treat as stage II breast cancer
Adenocarcinoma, poorly differentiated carcinoma	Women, peritoneal carcinomatosis (occasionally men?)	Treat as stage III ovarian cancer
Adenocarcinoma	Men, elevated PSA or blastic bone metastases	Treat as advanced prostate cancer
Adenocarcinoma, poorly differentiated carcinoma	Single metastatic lesion	Definitive local therapy (resection or radiation therapy [or both]) with or without chemotherapy
Adenocarcinoma	Colon cancer profile	Treat as metastatic colorectal cancer
Squamous cell carcinoma	Cervical adenopathy	Treat as locally advanced head or neck cancer
Squamous cell carcinoma	Inguinal adenopathy	Definitive local therapy (node dissection with or without radiation therapy) with or without chemotherapy
Poorly differentiated carcinoma	Young men with midline tumor or elevated hCG or AFP	Treat as extragonadal germ cell tumor
Neuroendocrine carcinoma, poorly differentiated	Diverse clinical presentations	Treat as advanced stage small cell lung cancer
Neuroendocrine carcinoma, well differentiated	Usually liver metastases	Treat as metastatic carcinoid tumor

AFP = α-fetoprotein; hCG = human chorionic gonadotropin; PSA = prostate-specific antigen.
From Hainsworth J, Greco FA. Approach to the patient with cancer. In: Goldman L, Schafer AI, eds. *Cecil Medicine*, 25th ed. Philadelphia: Elsevier; 2015.

Squamous Cell Carcinoma

Squamous cell carcinoma of unknown primary site is relatively uncommon. Most patients are middle aged or elderly with a long history of substantial use of alcohol or tobacco or both.

Cervical Adenopathy

When the cervical lymph nodes, especially in the upper or midcervical area, are involved with squamous cell carcinoma, a primary site should be suspected in the head and neck region (Chapter 176). Nevertheless, a complete endoscopic evaluation will not identify a primary tumor in about 15% of such patients. When the endoscopic evaluation is negative, PET scanning can identify a primary head and neck lesion in about 25% of such patients, so it should be part of the initial evaluation.

In patients with a squamous cell carcinoma of unknown primary site, concurrent chemotherapy and radiation therapy are recommended as for locally advanced squamous cell carcinoma arising in the head and neck.[33] Combined modality therapy results in 50 to 60% 5-year disease-free survival rates. A node larger than 2 cm and the presence of multiple involved lymph nodes are adverse prognostic features (Chapter 176).

Inguinal Adenopathy

Metastatic squamous cell cancer occasionally can be found in an inguinal lymph node. In most such cases the primary site can be identified in the perineal or anorectal area. For the occasional patient in whom no primary site is identified, local therapy with inguinal lymph node dissection, with or without radiation therapy, can result in long-term survival. Combined-modality treatment with concurrent chemotherapy and radiation therapy has improved survival and even led to cure in patients with several types of squamous cell carcinomas that originate in this region (e.g., cervix, anus, bladder). Although data are incomplete, a reasonable approach is the addition of chemotherapy with a platinum–5-fluorouracil regimen, as used for locally advanced carcinoma of the cervix (Chapter 184).

Poorly Differentiated Carcinoma

Extragonadal Germ Cell Cancer Syndrome

Young men who have clinical features suggestive of extragonadal germ cell tumors, such as tumors that are located in the mediastinum or retroperitoneum or tumors that are associated with elevated serum levels of human chorionic gonadotropin (hCG) or alpha fetoprotein, should be treated according to guidelines for extragonadal germ cell tumors (Chapter 185). Some of these patients can be proven to have germ cell tumors by identifying an i12p chromosomal abnormality even when the diagnosis is not possible with other standard pathologic techniques. Approximately 30 to 40% of such patients achieve complete responses and long-term survival after chemotherapy with cisplatin, etoposide, and bleomycin as used for advanced germ cell tumors.

Anaplastic Lymphoma

An appropriate initial pathologic evaluation should identify most histologically atypical lymphomas. Occasionally, immunohistochemical staining for leukocyte common antigen is negative or cannot be adequately performed in patients with anaplastic lymphoma. In some of these patients, the type of tumor can be identified using other immunohistochemical stains (e.g., Ki-1, CD-30), molecular genetic analysis (detection of immunoglobulin gene rearrangements), or molecular tumor profiling. All patients whose lymphomas are identified by special pathologic studies should be treated using standard guidelines for aggressive non-Hodgkin lymphoma (Chapter 171).

Neuroendocrine Carcinoma

In approximately 10% of poorly differentiated carcinomas, neuroendocrine features are identified by either immunohistochemical staining or electron microscopy. Treatment of these patients is as described for neuroendocrine carcinoma (see later).

Other Poorly Differentiated Carcinomas

Most patients with poorly differentiated carcinoma have no clinical or pathologic features that can be used to identify a specific treatment. Such patients have a poor prognosis, similar to that of patients who have adenocarcinoma of unknown primary site, and their treatment should follow similar guidelines.

Neuroendocrine Carcinoma

Poorly Differentiated Neuroendocrine Carcinoma or Small Cell Anaplastic Carcinoma

High-grade neuroendocrine tumors can be reliably identified using readily available immunohistochemistry stains. Although the origin of these tumors is unknown, they frequently are very sensitive to combination chemotherapy. For example, platinum–etoposide chemotherapy, as prescribed for small cell lung cancer (Chapter 177), can provide an overall response rate in approximately 60% of patients, including complete responses in 15 to 20% of patients. In patients who have locoregional disease, post-chemotherapy radiation therapy is also reasonable. Peptide receptor radionuclide therapy with ^{177}lutethium dotatate is also useful for the treatment of neuroendocrine tumors.

Low-Grade (Carcinoid-Type) Neuroendocrine Tumors

Some low-grade neuroendocrine tumors present at a metastatic site, usually in the liver and usually with histologic features that suggest a carcinoid tumor (Chapter 213) or an islet cell tumor of gastrointestinal origin (Chapter 211). The clinical syndromes may be dominated by the secretion and action of vasoactive peptides (e.g., serotonin, vasoactive intestinal peptide, gastrin). As with other carcinoid tumors, these tumors often are relatively indolent, so patients can often survive for several years despite multiple liver metastases. Unlike poorly differentiated neuroendocrine tumors, however, these tumors tend to be relatively resistant to chemotherapy, so intensive combination regimens should usually be avoided. Treatment, which should follow guidelines for metastatic carcinoid tumors (Chapter 213), may include somatostatin analogues, local ablative procedures (e.g., surgical resection, radiofrequency ablation, chemoembolization), targeted agents (e.g., sunitinib, everolimus), or fluorouracil-based chemotherapy regimens.

Empiric Chemotherapy

A substantial proportion of patients with adenocarcinoma or poorly differentiated carcinoma of unknown primary site do not fit into a defined clinical subset for which targeted treatment is available. In such patients, empiric chemotherapy (usually taxane–platinum or gemcitabine–platinum combinations) can provide modest benefit, with response rates of 30 to 45% and a median survival of 9 to 11 months. However, empiric chemotherapy regimens are best avoided, and patients are better served by the best possible site-specific treatment, guided by the tumor's likely site of origin based on molecular tumor profiling.

SURVIVORSHIP AND FOLLOW-UP

Approximately 4% of the U.S. population (≈14 million people) is living with a history of cancer, and about 60% of cancer survivors are age 65 years or older. As a result, a large number of individuals are living longer as cancer survivors from the conclusion of active treatment to the time of recurrence or death from another condition. These patients have specific needs, including a defined program of surveillance to detect recurrence or second cancers and the late effects of cancer treatment; intervention to treat the consequences of the cancer and its treatment (such as lymphedema, fatigue, and psychosocial distress); prevention of new cancers by changes in diet, behavior, and physical activity[34,A9] (Chapter 165); and the institution of a coordinated program of care that may require a variety of specialty services.[35] Long-term follow-up can be optimized by the provision of a survivorship care plan that provides a comprehensive summary of all diagnostic and therapeutic procedures undergone, toxicities experienced, and therapeutic outcomes, as well as a specific program for stress management[36] and for individualized follow-up care.[A10] Although definitive follow-up regimens do not exist for most cancers, evidence-based templates for common malignancies have been developed by the American Society of Clinical Oncology and the National Comprehensive Cancer Network. In addition, issues of survivorship also affect caregivers, who often experience a high degree of psychological distress during and after the period of active treatment.

165 EPIDEMIOLOGY OF CANCER

RULLA M. TAMIMI

CANCER BURDEN AND TRENDS

GLOBAL STATISTICS

Cancer is a major public health concern worldwide. The World Health Organization (WHO) estimates that cancer is the first or second leading cause of death before age 70 years in the majority of countries.[1] In 2020, 19.3 million new cases of cancer were diagnosed globally, and almost 10 million deaths were attributable to cancer (Fig. 165-1). Among women, breast cancer (24.5%) is the leading cause of incident cancer followed by colorectal cancer (9.4%), and breast cancer (15.5%) is the leading cause of cancer mortality followed by lung cancer (13.7%). Among men, lung cancer (14.3%) is the leading cause of incident cancer followed by prostate cancer (14.1%), and lung cancer (21.5%) is the leading cause of cancer mortality followed by liver cancer (10.5%). The burden of cancer varies substantially by geographic region and is impacted by factors such as the age of the population, the prevalence of cancer risk factors, screening and treatment practices, and a country's social and economic development. For example, the incidence and mortality of cervical cancer (Chapter 184) is quite low in high-income countries compared with low-income countries because of cervical cancer screening and vaccination for human papillomavirus.

UNITED STATES STATISTICS

In the United States, cancer is the second leading cause of death after heart disease. In 2020, more than 1.8 million new cases of cancer were diagnosed, and over 600,000 deaths were attributed to cancer. Over the past 50 years, the United States has experienced substantial changes in the incidence of several types of cancer as a reflection of patterns of exposure to risk factors as well as access to and utilization of cancer screening (Fig. 165-2).[2,3] For example, the dramatic increase in the incidence of prostate cancer (Chapter 186) in the 1990s reflected widespread prostate-specific antigen (PSA) testing in men and the resulting detection of asymptomatic disease. This increase was then followed by a dramatic decline in the reported incidence of prostate cancer in 2007 to 2014, largely attributable to changes in the screening guidelines of the United States Preventive Task Force (USPTF), which recommended against routine PSA screening because of concerns regarding overdiagnosis and overtreatment. Similar to prostate cancer, the incidence of breast cancer (Chapter 183) increased in the late 1980s with widespread adoption of mammographic screening. However, incidence rates for breast cancer have remained relatively stable, with slight increases observed in the last 20 years, thought to be attributable to continued increases in body mass index and trends in reproductive patterns (e.g., later age at first birth and lower parity). The incidence rates for colorectal cancer (Chapter 179) have been declining for both men and women since the mid-1980s, likely reflecting colorectal cancer screening practices that can detect precancerous lesions and prevent cancers from occurring. Incidence rates for lung cancer (Chapter 177) closely mirror smoking patterns in the population, although the decline in incidence rates is more pronounced in men than in women. Some of this sex difference may be related to differences in the initiation and cessation of smoking, but a greater percentage of lung cancers in women occur in nonsmokers.

By 2040, estimates suggest that breast cancer will be the most common cancer in the United States, followed by melanoma, lung cancer, and colorectal cancer. In terms of cancer death, lung cancer is projected to remain first, followed by pancreatic cancer, liver and biliary cancer, colon cancer, and breast cancer.[4]

CANCER RISK FACTORS

DEMOGRAPHIC FACTORS

Increasing age is an important risk factor for most cancers, with more than one-third of new cancers in the United States occurring in people age 75 years or older. Age likely represents the accumulation of biologic changes that influence carcinogenesis (Chapter 166). However, these biologic changes occur at different rates in different people depending on their underlying genetics and exposures across the life course. Additionally, cancers at different sites have unique patterns of incidence across the age continuum.

For cancers that occur in both men and women, cancer incidence rates tend to be higher in men (Fig. 165-2). At least some of these sex differences may be attributable to differences in the prevalence of relevant risk factors. For example, the prevalence of smoking has changed over time, but current smoking and smoking-related cancers continue to be higher in men in most countries.

Cancer incidence and mortality rates vary by race and ethnicity.[5] These differences are multifactorial and reflect differences in risk factors and access to high-quality preventive care, screening, and cancer treatments. Across all cancer sites, Black men in the United States have about a 20% higher cancer death rate than do White men. Similarly, Black women in the United States have about a 12% higher death rate than do White women, despite having a lower incidence rate. Black and Hispanic patients are often diagnosed at later stages of cancer, in part reflecting lower rates of screening. Overall cancer mortality rates mask disparities for specific cancers. For example, although Hispanic and Asian individuals have lower overall cancer mortality, their incidence and mortality of liver cancer are higher than in the White population.

SURVIVORSHIP AND FOLLOW-UP

Approximately 4% of the U.S. population (≈14 million people) is living with a history of cancer, and about 60% of cancer survivors are age 65 years or older. As a result, a large number of individuals are living longer as cancer survivors from the conclusion of active treatment to the time of recurrence or death from another condition. These patients have specific needs, including a defined program of surveillance to detect recurrence or second cancers and the late effects of cancer treatment; intervention to treat the consequences of the cancer and its treatment (such as lymphedema, fatigue, and psychosocial distress); prevention of new cancers by changes in diet, behavior, and physical activity[34,A9] (Chapter 165); and the institution of a coordinated program of care that may require a variety of specialty services.[35] Long-term follow-up can be optimized by the provision of a survivorship care plan that provides a comprehensive summary of all diagnostic and therapeutic procedures undergone, toxicities experienced, and therapeutic outcomes, as well as a specific program for stress management[36] and for individualized follow-up care.[A10] Although definitive follow-up regimens do not exist for most cancers, evidence-based templates for common malignancies have been developed by the American Society of Clinical Oncology and the National Comprehensive Cancer Network. In addition, issues of survivorship also affect caregivers, who often experience a high degree of psychological distress during and after the period of active treatment.

165 EPIDEMIOLOGY OF CANCER

RULLA M. TAMIMI

CANCER BURDEN AND TRENDS

GLOBAL STATISTICS

Cancer is a major public health concern worldwide. The World Health Organization (WHO) estimates that cancer is the first or second leading cause of death before age 70 years in the majority of countries.[1] In 2020, 19.3 million new cases of cancer were diagnosed globally, and almost 10 million deaths were attributable to cancer (Fig. 165-1). Among women, breast cancer (24.5%) is the leading cause of incident cancer followed by colorectal cancer (9.4%), and breast cancer (15.5%) is the leading cause of cancer mortality followed by lung cancer (13.7%). Among men, lung cancer (14.3%) is the leading cause of incident cancer followed by prostate cancer (14.1%), and lung cancer (21.5%) is the leading cause of cancer mortality followed by liver cancer (10.5%). The burden of cancer varies substantially by geographic region and is impacted by factors such as the age of the population, the prevalence of cancer risk factors, screening and treatment practices, and a country's social and economic development. For example, the incidence and mortality of cervical cancer (Chapter 184) is quite low in high-income countries compared with low-income countries because of cervical cancer screening and vaccination for human papillomavirus.

UNITED STATES STATISTICS

In the United States, cancer is the second leading cause of death after heart disease. In 2020, more than 1.8 million new cases of cancer were diagnosed, and over 600,000 deaths were attributed to cancer. Over the past 50 years, the United States has experienced substantial changes in the incidence of several types of cancer as a reflection of patterns of exposure to risk factors as well as access to and utilization of cancer screening (Fig. 165-2).[2,3] For example, the dramatic increase in the incidence of prostate cancer (Chapter 186) in the 1990s reflected widespread prostate-specific antigen (PSA) testing in men and the resulting detection of asymptomatic disease. This increase was then followed by a dramatic decline in the reported incidence of prostate cancer in 2007 to 2014, largely attributable to changes in the screening guidelines of the United States Preventive Task Force (USPTF), which recommended against routine PSA screening because of concerns regarding overdiagnosis and overtreatment. Similar to prostate cancer, the incidence of breast cancer (Chapter 183) increased in the late 1980s with widespread adoption of mammographic screening. However, incidence rates for breast cancer have remained relatively stable, with slight increases observed in the last 20 years, thought to be attributable to continued increases in body mass index and trends in reproductive patterns (e.g., later age at first birth and lower parity). The incidence rates for colorectal cancer (Chapter 179) have been declining for both men and women since the mid-1980s, likely reflecting colorectal cancer screening practices that can detect precancerous lesions and prevent cancers from occurring. Incidence rates for lung cancer (Chapter 177) closely mirror smoking patterns in the population, although the decline in incidence rates is more pronounced in men than in women. Some of this sex difference may be related to differences in the initiation and cessation of smoking, but a greater percentage of lung cancers in women occur in nonsmokers.

By 2040, estimates suggest that breast cancer will be the most common cancer in the United States, followed by melanoma, lung cancer, and colorectal cancer. In terms of cancer death, lung cancer is projected to remain first, followed by pancreatic cancer, liver and biliary cancer, colon cancer, and breast cancer.[4]

CANCER RISK FACTORS

DEMOGRAPHIC FACTORS

Increasing age is an important risk factor for most cancers, with more than one-third of new cancers in the United States occurring in people age 75 years or older. Age likely represents the accumulation of biologic changes that influence carcinogenesis (Chapter 166). However, these biologic changes occur at different rates in different people depending on their underlying genetics and exposures across the life course. Additionally, cancers at different sites have unique patterns of incidence across the age continuum.

For cancers that occur in both men and women, cancer incidence rates tend to be higher in men (Fig. 165-2). At least some of these sex differences may be attributable to differences in the prevalence of relevant risk factors. For example, the prevalence of smoking has changed over time, but current smoking and smoking-related cancers continue to be higher in men in most countries.

Cancer incidence and mortality rates vary by race and ethnicity.[5] These differences are multifactorial and reflect differences in risk factors and access to high-quality preventive care, screening, and cancer treatments. Across all cancer sites, Black men in the United States have about a 20% higher cancer death rate than do White men. Similarly, Black women in the United States have about a 12% higher death rate than do White women, despite having a lower incidence rate. Black and Hispanic patients are often diagnosed at later stages of cancer, in part reflecting lower rates of screening. Overall cancer mortality rates mask disparities for specific cancers. For example, although Hispanic and Asian individuals have lower overall cancer mortality, their incidence and mortality of liver cancer are higher than in the White population.

ABSTRACT

Cancer is the first or second leading cause of death before age 70 years in the majority of countries. In 2020, 19.3 million new cases of cancer were diagnosed globally, and almost 10 million deaths were attributable to cancer. Among women, breast cancer (24.5%) is the leading cause of incident cancer and cancer mortality (15.5%). Among men, lung cancer (14.3%) is the leading cause of incident cancer and cancer mortality (21.5%). The burden of cancer varies substantially by geographic region and is impacted by factors such as the age of the population, the prevalence of cancer risk factors, screening and treatment practices, and social and economic factors. Tobacco use, in particular cigarette smoking, is associated with a number of cancer sites and is a leading cause of death from cancer. Excess body weight is also associated with cancer at multiple sites. Other cancer risk factors include diet, alcohol intake, physical activity, infectious agents, hormones, and ionizing radiation. This chapter also discusses the importance of molecular and genetic epidemiology, how the integration of molecular tools has allowed for robust insights into the causes of cancer, and how cancer control can reduce the burden of cancer in the population.

Global Cancer Statistics 2020: GLOBOCAN estimates of incidence and mortality worldwide for 36 cancers in 185 countries. *CA Cancer J Clin*. 2021;71:209-249.)

ENVIRONMENTAL AND LIFESTYLE FACTORS

Potentially modifiable environmental and lifestyle risk factors are major contributors to the development of cancer.[6,7]

Tobacco

Tobacco use (Chapter 363), and in particular cigarette smoking, is a leading cause of death from cancer. In the United States, almost 30% of cancer deaths are estimated to be attributable to tobacco smoking.[8] Strong evidence links tobacco smoking as a cause for a number of cancers, including lung, oral cavity, nasal cavity, nasopharynx, oropharynx, hypopharynx, larynx, esophagus, stomach, pancreas, liver, kidney, ureter, bladder, and cervix, as well as myeloid leukemia. Chewing tobacco also markedly increases the risk of oral and pharyngeal cancers. Significant advances in tobacco control have resulted in dramatic declines in the prevalence of smoking. Despite these successes, an estimated 22% of the global adult population smokes tobacco. Smoking rates vary widely by region and sex. China has the highest prevalence of adult male smoking (29%), whereas the United States has the highest prevalence of adult female smoking (10%).

Despite success in efforts to reduce cigarette smoking, the emergence of new tobacco products (e.g., vapes, sheesha, flavored tobacco products) has created new public health and equity issues. Additionally, tobacco control has been less successful in specific segments of the population, especially related to sexual orientation and gender identity (Chapter 215).

Obesity and Height

Consistent evidence links excess body weight (Chapter 201) with the risk of cancer at multiple sites. The risk is strongest (a three-fold increase in risk) for endometrial and esophageal cancers and more modest (relative risks of 1.5 to 3.0) for cancers of the kidney, liver, pancreas, and stomach, as well as for multiple myeloma and meningioma. The lowest relative risks (1.0 to 1.5) are for colorectal, postmenopausal breast, gallbladder, ovarian, and thyroid cancers.

The biologic mechanisms that have been proposed to underlie these associations include chronic inflammation, hyperinsulinemia/insulin resistance, insulin-like growth factor (IGF)-1 pathways, and the impact of obesity on circulating sex steroids. Given the strong association between adiposity and many cancers, maintaining a healthy body weight is an important recommendation for cancer prevention. For example, the marked weight loss after bariatric surgery is associated with a significant reduction in the incidence of cancer.[9]

Strong evidence links certain cancers with adult height independent of obesity. For example, adult height is positively associated with the risks of colorectal, ovarian, and breast cancer.[10] In a nationwide study in Sweden, every 10 cm increase in height was associated with about a 20% increased risk of cancer in women and about a 10% increased risk of cancer in men.[11] All cancer sites showed a positive association, with the strongest relative risk (35 to 40%) for malignant melanoma. Height may reflect a larger number of cells at risk of transformation, or adult height may reflect energy intake or exposures to growth factors early in life. For example, levels of IGF-1 in childhood are strongly correlated with height.

Diet and Alcohol

Although the association between adiposity and the risk of cancer is consistent across a number of cancer sites, the association between food groups and nutrients is not. Reasonable prevention recommendations specifically related to diet include: eat a diet rich in whole grains, vegetables, fruits, and beans; limit consumption of fast foods and/or other processed foods high in fat, starches, or sugars; limit consumption of red and processed meats;[12] and limit consumption of sugar-sweetened beverages (Chapter 13).

Alcohol (Chapter 364) is responsible for about 4% of cancers worldwide.[13] The magnitude of association is strongest for oral and pharyngeal cancers as well as esophageal squamous cell carcinoma, but alcohol is also associated with liver and colorectal cancer. For female breast cancer, the association is modest, with a relative risk of 1.6. No convincing evidence links alcohol to other common cancers such as prostate or lung cancers.

Most epidemiologic studies show a dose–response relationship, with increasing amounts of alcohol conveying higher risks regardless of the type of alcohol consumed. The primary hypothesized mechanism is via metabolites,

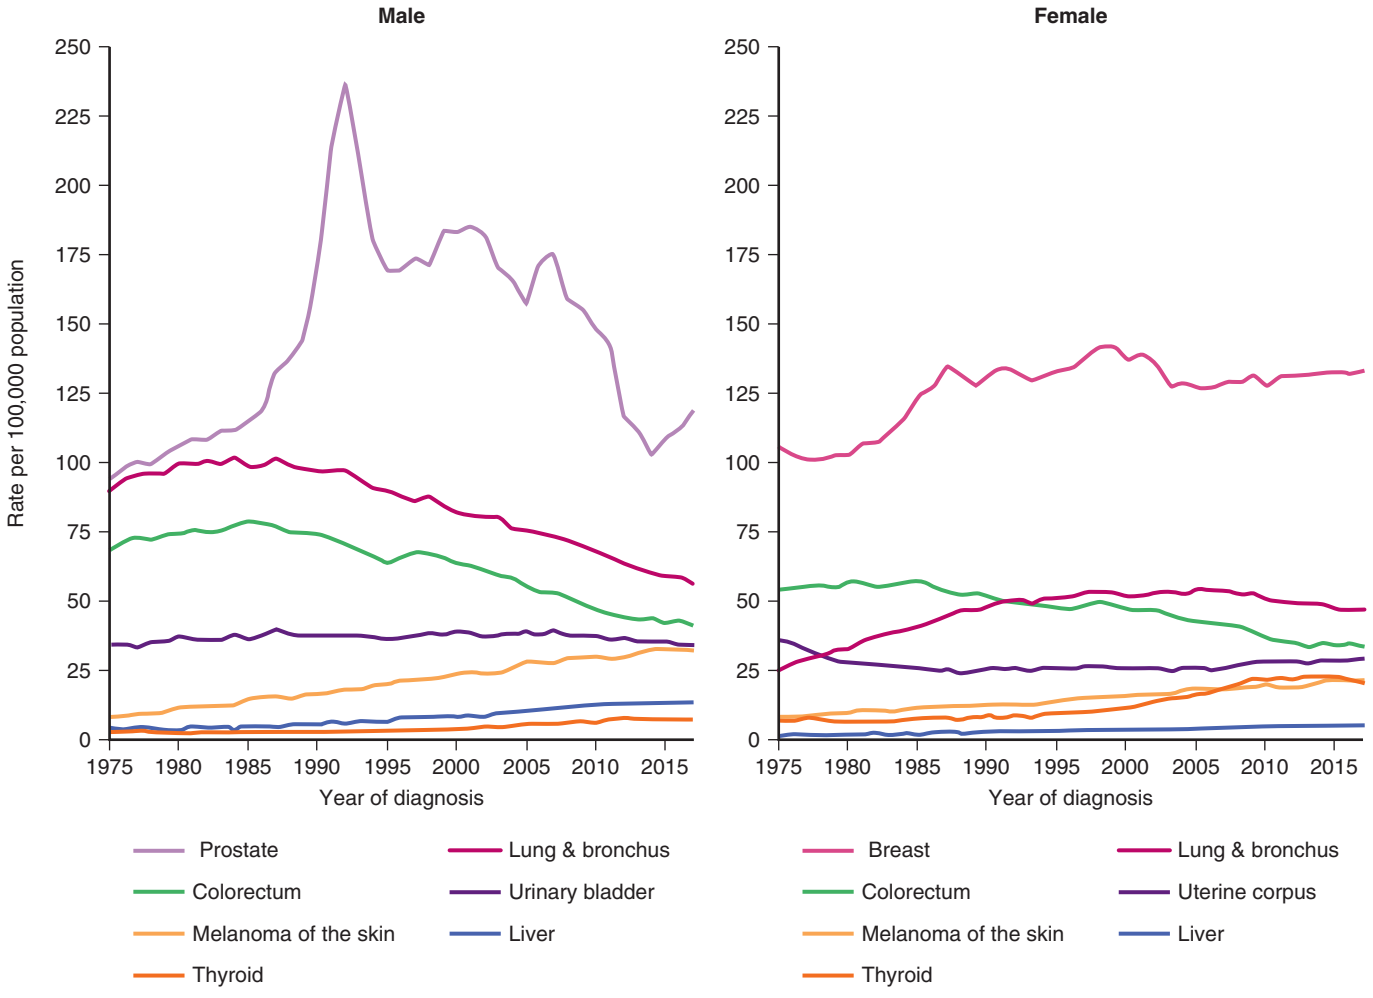

FIGURE 165-2. Trends in incidence rates for selected cancers by sex, United States, 1975-2017. (Reproduced from Siegel RL, Miller KD, Fuchs HE, et al. Cancer statistics, 2021. *CA Cancer J Clin*. 2021;71:7-33.)

such as acetaldehyde, which have carcinogenic and mutagenic properties. Alcohol's link to breast cancer probably is partly related to its association with increased levels of total and bioavailable estrogen in premenopausal women, as well as elevated plasma levels of estrogen and increased plasma estradiol levels in postmenopausal women. Additionally, alcohol consumption can indirectly impact the risk of cancer by its association with increases in body mass index.

Physical Activity

Physical activity (Chapter 14) has been hypothesized to reduce the risk of cancer, but the epidemiologic data are not entirely consistent, perhaps because of imperfect measurement of physical activity and the difficulty of separating the direct effects of physical activity from the effects of concomitant adiposity and obesity. The primary hypothesized mechanisms relate to the impact of physical activity on circulating hormones (e.g., sex steroids, insulin and insulin-like growth factors, adipokines), inflammation, immune function, and oxidative stress.

For example, pooled data suggest that higher levels of leisure time physical activity are associated with a reduced risk of 13 cancers,[14] with the strongest associations (>20% reduced risk when comparing the 90th percentile to the 10th percentile) for esophageal adenocarcinoma and cancers of the liver, lung, kidney, gastric cardia, and endometrium, as well as for myeloid leukemia. Moderate associations (10 to 20% reduced risk) are seen for colon, head and neck, rectal, bladder, and breast cancers, as well as for multiple myeloma. After adjusting for body mass index, endometrial, liver, and gastric cancer were no longer significantly associated with physical activity, whereas the relative risk for other cancer sites were only modestly reduced, thereby suggesting that physical activity is a risk factor independent of its relationship to body mass index. The relationship between increased physical activity and a reduced risk for breast cancer and colorectal cancer has also been confirmed using mendelian randomization analysis.[15]

Given the robust evidence and wide impact on reduced risk of several cancer sites, promoting physical activity should be a key component of cancer prevention efforts. For cancer prevention, adults should get at least 2.5 hours/week of moderate-intensity physical activity or 1.25 hours/week of vigorous-intensity physical activity.

Infectious Agents

Eleven infectious pathogens are classified as group 1 carcinogens (i.e., carcinogenic to humans), and an estimated 13% of all cancer cases worldwide are attributable to infections.[16]

The four agents with the greatest impact on cancer in rank order are *Helicobacter pylori* (non–cardia gastric adenocarcinoma; Chapter 178), high-risk human papillomavirus (Chapter 344; cervix, head and neck, and anal carcinoma), hepatitis B virus (Chapter 135), and hepatitis C virus. Almost all cervical cancers (Chapter 184) are attributable to high-risk subtypes of human papillomavirus. Hepatitis B virus is a DNA virus that can cause hepatocellular carcinoma; among carriers of hepatitis B virus, the lifetime risk of hepatocellular carcinoma (Chapter 181) is estimated to be 10 to 25%. Together, these four infectious agents explain >90% of all infection-related cancers globally. The age-standardized incidence rates for infection-attributable cancers vary considerably by geographic region. For example, although *H. pylori* is the most important infectious cause of cancer globally, the age-standardized incidence rates vary by more than five-fold from Eastern Asia, where they are highest, to North America, where they are lowest.

HORMONES

Endogenous Estrogens and Androgens

Several lines of evidence suggest that estrogens play a central role in the cause of female cancers. For example, the risk of breast cancer increases with increasing circulating levels of estrogen. Estrone, estrone sulfate, and free estradiol are similarly related to risk.

Androgens have been hypothesized to increase the risk of breast cancer either directly, by increasing the growth and proliferation of breast cancer cells, or indirectly, by their conversion to estrogen. In postmenopausal women, testosterone and other androgens have been positively associated with the risk of breast cancer. Among premenopausal women, data are much more limited, but statistically significant positive associations are also seen for testosterone, androstenedione, and dehydroepiandrosterone.[17]

Androgens are implicated in cancers of the prostate and breast. Total castration and androgen suppression are successful treatments for advanced prostate cancer,[18] but the association of circulating free testosterone with the risk of developing prostate cancer is more modest.[19]

Exogenous Hormones

Worldwide, the estimated 151 million women who use oral contraceptives represent 16% of women of reproductive age.[20] Most combined oral contraceptives contain ethinyl estradiol (or mestranol, which is metabolized to ethinyl estradiol; Chapter 220) plus a progestin. Patterns of use have changed considerably over time, with both increased duration of use and a trend toward younger age at first use.

The use of oral contraceptives is associated with a modest increased risk of breast cancer for current or recent users. Among women younger than age 50 years, the risk of breast cancer is about 20% higher in women who are current or recent users of hormonal contraceptives compared with nonusers, and a longer duration of use is associated with increased risk.[21] In contrast, the use of oral contraceptives has been associated with lower risks of colorectal, endometrial, and ovarian cancers.[22]

Some menopausal hormone therapies also increase the risk of breast cancer, but formulations and patterns of use have varied over time. The addition of a progestin to estrogen regimens has become increasingly common to minimize or eliminate the increased risk of endometrial hyperplasia and cancer associated with unopposed estrogens. Accumulating data suggest that the addition of a progestin increases the risk of breast cancer beyond that associated with estrogen alone, with stronger associations observed with longer durations of use. Furthermore, different formulations, routes of administration, and regimens may impact the association with breast cancer.[23] Postmenopausal hormonal therapy also appears to increase the risk of ovarian cancer.[24] By comparison, postmenopausal hormone therapies are associated with lower risks of colorectal, esophageal, and gastric cancers. Given the substantial evidence implicating postmenopausal hormone therapies in breast cancer, women and their physicians should carefully consider their risks and benefits (Chapter 222).

IONIZING RADIATION

Exposure to ionizing radiation (Chapter 18) causes somatic DNA mutations. The long-term effects of high levels of ionizing radiation on the risk of cancer is best estimated from people who were exposed to the atomic bombings in Japan in 1945 and to large nuclear disasters in Chernobyl and Fukushima. In atomic bomb survivors in Hiroshima and Nagasaki, excess cases of leukemia were observed by 3 years after exposure, and an excess risk of solid tumors was observed by 10 years after exposure. Sites of excess risk included bladder, breast (female), lung, brain, thyroid, colon, esophagus, ovary, stomach, and liver. For all of these types of cancer, the magnitude of risk increased as the radiation dose increased and as the age at exposure decreased.

MOLECULAR AND GENETIC EPIDEMIOLOGY

The integration of molecular tools in epidemiologic studies has allowed for robust insights into the causes of cancer. For example, aflatoxin is produced by a fungus, which can contaminate stored grain and nuts. Although animal studies demonstrated aflatoxin was carcinogenic, the association between the dietary intake of aflatoxin and liver cancer in humans was difficult to demonstrate until biomarkers of exposure (e.g., urinary metabolites of aflatoxin and DNA adducts reflecting exposure) were identified and showed strong evidence of a causal association.

The assessment of biomarkers for cancer epidemiologic research spans the continuum of disease from germline genetic susceptibility, markers of exposure (e.g., presence of cancer causing virus or cotinine), markers of internal dose (e.g., DNA adducts), markers of effective dose (e.g., somatic mutational patterns), or markers of tumor heterogeneity and prognosis (e.g., molecular subtypes). The landscape of molecular epidemiology has evolved over time as newer tools have demonstrated validity in stored biospecimens. Large-scale genome-wide association studies (GWAS) studies have led to the identification of single nucleotide polymorphisms (SNPs) that are associated with disease. Polygenic risk scores can incorporate multiple SNPs associated with a disease into a single score. Inclusion of a polygenic risk score to risk assessment models can significantly improve the ability to predict the development of breast and prostate cancer and may help develop more personalized cancer screening protocols.

CANCER CONTROL: PREVENTION AND TREATMENT

Cancer control refers to reducing the burden of cancer in the population, whether by reducing the incidence of and mortality from cancer or by improving the quality of life for patients who are being treated for and living with cancer (Fig. 165-3). Cancer prevention, screening, and early detection are critical for reducing the incidence and mortality from cancer.

PRIMARY PREVENTION

Primary prevention refers to strategies targeted at reducing exposure to established cancer risk factors. Cancer prevention efforts can be multifaceted by targeting individuals, medical recommendations, schools, neighborhood planning, and federal policies. Most notably, tobacco control efforts (Chapter 363) have had a substantial impact on the declining incidence and mortality rates attributable to lung cancer. Tobacco control efforts have included educational efforts to reduce the initiation of smoking and to increase the uptake of smoking cessation programs (Chapter 363). Policy changes have resulted in the implementation of tobacco-free public places, workplaces, and multiunit residential settings.

Vaccinations against carcinogenic infections are another successful approach for reducing the incidence of cancer. Vaccination programs for human papillomavirus (Chapter 344) and hepatitis B virus (Chapter 134) are two strategies to reduce the incidence rates of cervical and liver cancer,

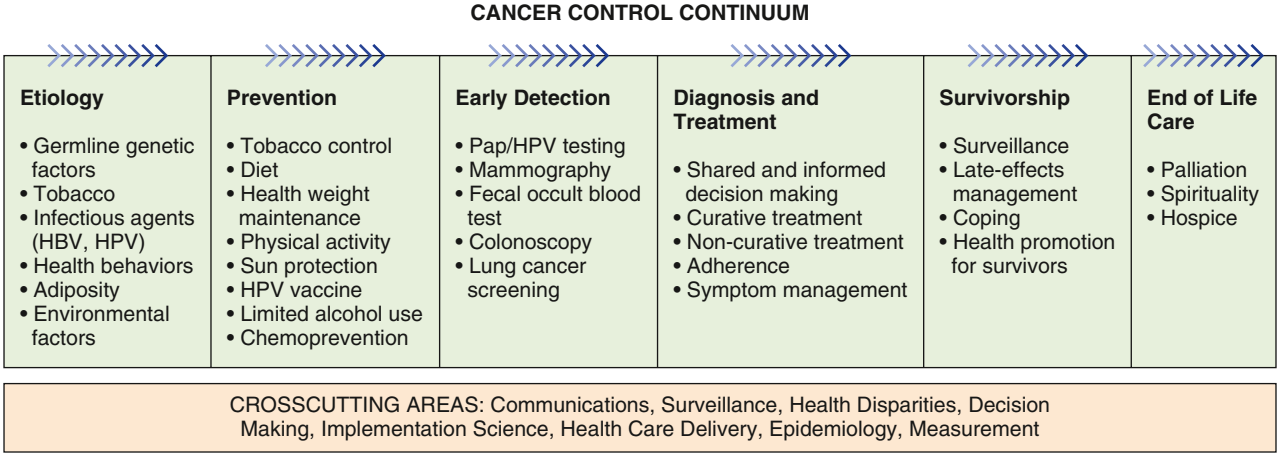

FIGURE 165-3. The Cancer Control Continuum. Examples and opportunities to impact cancer morbidity and mortality along the continuum. HBV = hepatitis B virus; HPV = human papillomavirus.

respectively. For example, a nationwide neonatal hepatitis B virus immunization program launched in Taiwan in 1984 reduced the incidence rate for hepatocellular carcinoma by 80%, and the mortality rate declined by over 90%.[25] Several clinical trials have demonstrated the efficacy and safety of vaccines for human papillomavirus,[A1] with data already showing reductions in cervical cancer[A2] and human papillomavirus–related oropharyngeal cancer.[A3] Because large-scale nationwide human papillomavirus vaccination programs were not initiated until 2007, it is too early to observe major declines in cancer incidence rates given the latency period, but widespread vaccination programs could lead to the elimination of cervical cancer. Major challenges that remain are related to the implementation of programs to improve both access and adherence.

Other established modifiable cancer risk factors include obesity (Chapter 201), physical inactivity (Chapter 14), poor diet (Chapter 13), and alcohol consumption (Chapter 364). Diets and behaviors aimed at maintaining healthy weights throughout life have the potential to reduce the risk of several cancers. Limiting alcohol consumption and being physically active also can reduce the risk of cancer.

SECONDARY PREVENTION

Secondary prevention refers to strategies aimed at reducing mortality from cancer. Screening is often a central part of secondary prevention because the goal of screening is to detect cancer in a presymptomatic state. Screening programs are well established for a number of cancers. For cervical cancer, initial success was observed with widespread screening using the Papanicolaou smear, and human papillomavirus–based screening strategies have demonstrated even greater efficacy when compared with cytology alone (Chapter 184).[A4] The incidence rates for colorectal cancer have been falling in the United States (see Fig. 165-2), largely due to the success of screening programs (with stool-based tests, sigmoidoscopy, and colonoscopy), which are now recommended to begin at ages 45 to 49 years (Chapters 12 and 179).[A5]

Widespread PSA testing for prostate cancer (Chapter 186) and mammography for breast cancer (Chapter 183) have resulted in dramatic increases in the reported incidence of these two cancers. Both approaches have also likely led to reductions in cancer-specific mortality, despite concerns about overdiagnosis and overtreatment of some of the lesions detected through these screening programs. Given concerns regarding harms related to PSA screening, the U.S. Preventive Services Task Force modified its recommendations in 2018 to advise that the decision to undergo PSA screening should be made at the individual level through shared decision making.[A6]

Lung cancer screening with low-dose computed tomographic scanning is beneficial for high-risk individuals, in whom it can reduce mortality by about 25 to 33% in the following 10 years.[A7,A8] The U.S. Preventive Services Task Force guidelines now recommend it for persons who are at high risk (e.g., adults ages 50 to 80 years with a >20 pack-year smoking history who either currently smoke or have quit within the past 15 years) of lung cancer (Chapters 12 and 177).[26] Unfortunately, the uptake of lung cancer screening has been slow, especially in diverse populations,[27] with <5% of eligible persons undergoing screening,[28] presumably reflecting a lack of awareness on the part of the physician and the patient, confusion regarding recommendations, limited access to screening, and the stigma associated with smoking and lung cancer.[29]

TREATMENT

The availability of cancer treatments, including surgery, radiation, and chemotherapy, varies significantly across the world, with fewer treatments in lower-income countries (Chapter 5) and by socioeconomic status and ethnicity even in higher-income countries (Chapter 4). Access to high-quality cancer care impacts patients' outcomes and survival. As treatment improves, the prevalence of cancer rises, thereby emphasizing the need to addresses cancer survivorship care (Chapter 164).

166 CANCER BIOLOGY AND GENETICS

BEN HO PARK

INTRODUCTION

Cancer is a collection of many different diseases and is often not uniformly categorized by even the tissue of origin. For example, hormone receptor–positive breast cancers are distinct in biology, prognosis, and treatment compared with hormone receptor–negative breast malignancies. A unifying feature shared by all human cancers is that they have a genetic basis, even though familial cancer syndromes are relatively uncommon compared with sporadic cancers. However, both heritable and sporadic cancers require the accumulation of DNA mistakes or alterations that lead to a step-wise progression of events, ultimately resulting in cancer. These DNA alterations are typically classified as mutations, copy number changes, and gene rearrangements. Cancer also results when DNA undergoes epigenetic changes that do not involve alterations to the DNA sequence but produce modifications that result in either the silencing or activation of genes in an aberrant fashion.

CANCER IS A DISEASE OF CUMULATIVE DNA ALTERATIONS

When the balance of cell proliferation as compared with cell death or quiescence is perturbed, either due to abnormally increased proliferation or to decreased cell death or stasis, the initial steps of carcinogenesis have begun. Genes that mediate cell proliferation and cell death are often the early drivers of cancer, and many of these genes are mutated or altered in diverse types of cancer.

Two broad categories of cancer genes are termed *oncogenes* and *tumor suppressor genes*. Oncogenes, which are the accelerators of cancer growth, drive abnormal cell proliferation through various mechanisms. Common oncogenes that are often mutated or altered in human cancers include *KRAS*, *BRAF*, *PIK3CA*, and *ERBB2* (HER2). The functions of oncogenes are diverse, but many mutations and alterations that occur in oncogenes constitutively activate critical growth-promoting pathways that then drive cellular proliferation. Conversely, tumor suppressor genes act as the brakes of cell growth. Their normal function is to control cell cycling by monitoring and stopping proliferation when appropriate. Any disruption in the function of tumor suppressor genes would predictably lead to a net gain in cell numbers, possibly even without additional contributions of increased cell proliferation. Examples of tumor suppressor genes commonly mutated in human cancers include *TP53*, *CDKN2A*, *CDKN2B*, and others. Most cancers have genetic alterations involving both tumor suppressor genes and oncogenes, but the types of genetic alterations and consequences for therapies can vary dramatically between different malignancies.

DNA ALTERATIONS IN ONCOGENES AND TUMOR SUPPRESSOR GENES

Given the distinct yet complementary roles of oncogenes and tumor suppressor genes, it is perhaps not surprising that certain types of genetic alterations are associated more frequently with one or the other class of genes. Activating mutations within oncogenes, for example, tend to be heterozygous (i.e., only

respectively. For example, a nationwide neonatal hepatitis B virus immunization program launched in Taiwan in 1984 reduced the incidence rate for hepatocellular carcinoma by 80%, and the mortality rate declined by over 90%.[25] Several clinical trials have demonstrated the efficacy and safety of vaccines for human papillomavirus,[A1] with data already showing reductions in cervical cancer[A2] and human papillomavirus–related oropharyngeal cancer.[A3] Because large-scale nationwide human papillomavirus vaccination programs were not initiated until 2007, it is too early to observe major declines in cancer incidence rates given the latency period, but widespread vaccination programs could lead to the elimination of cervical cancer. Major challenges that remain are related to the implementation of programs to improve both access and adherence.

Other established modifiable cancer risk factors include obesity (Chapter 201), physical inactivity (Chapter 14), poor diet (Chapter 13), and alcohol consumption (Chapter 364). Diets and behaviors aimed at maintaining healthy weights throughout life have the potential to reduce the risk of several cancers. Limiting alcohol consumption and being physically active also can reduce the risk of cancer.

SECONDARY PREVENTION

Secondary prevention refers to strategies aimed at reducing mortality from cancer. Screening is often a central part of secondary prevention because the goal of screening is to detect cancer in a presymptomatic state. Screening programs are well established for a number of cancers. For cervical cancer, initial success was observed with widespread screening using the Papanicolaou smear, and human papillomavirus–based screening strategies have demonstrated even greater efficacy when compared with cytology alone (Chapter 184).[A4] The incidence rates for colorectal cancer have been falling in the United States (see Fig. 165-2), largely due to the success of screening programs (with stool-based tests, sigmoidoscopy, and colonoscopy), which are now recommended to begin at ages 45 to 49 years (Chapters 12 and 179).[A5]

Widespread PSA testing for prostate cancer (Chapter 186) and mammography for breast cancer (Chapter 183) have resulted in dramatic increases in the reported incidence of these two cancers. Both approaches have also likely led to reductions in cancer-specific mortality, despite concerns about overdiagnosis and overtreatment of some of the lesions detected through these screening programs. Given concerns regarding harms related to PSA screening, the U.S. Preventive Services Task Force modified its recommendations in 2018 to advise that the decision to undergo PSA screening should be made at the individual level through shared decision making.[A6]

Lung cancer screening with low-dose computed tomographic scanning is beneficial for high-risk individuals, in whom it can reduce mortality by about 25 to 33% in the following 10 years.[A7,A8] The U.S. Preventive Services Task Force guidelines now recommend it for persons who are at high risk (e.g., adults ages 50 to 80 years with a >20 pack-year smoking history who either currently smoke or have quit within the past 15 years) of lung cancer (Chapters 12 and 177).[26] Unfortunately, the uptake of lung cancer screening has been slow, especially in diverse populations,[27] with <5% of eligible persons undergoing screening,[28] presumably reflecting a lack of awareness on the part of the physician and the patient, confusion regarding recommendations, limited access to screening, and the stigma associated with smoking and lung cancer.[29]

TREATMENT

The availability of cancer treatments, including surgery, radiation, and chemotherapy, varies significantly across the world, with fewer treatments in lower-income countries (Chapter 5) and by socioeconomic status and ethnicity even in higher-income countries (Chapter 4). Access to high-quality cancer care impacts patients' outcomes and survival. As treatment improves, the prevalence of cancer rises, thereby emphasizing the need to addresses cancer survivorship care (Chapter 164).

166 CANCER BIOLOGY AND GENETICS

BEN HO PARK

INTRODUCTION

Cancer is a collection of many different diseases and is often not uniformly categorized by even the tissue of origin. For example, hormone receptor–positive breast cancers are distinct in biology, prognosis, and treatment compared with hormone receptor–negative breast malignancies. A unifying feature shared by all human cancers is that they have a genetic basis, even though familial cancer syndromes are relatively uncommon compared with sporadic cancers. However, both heritable and sporadic cancers require the accumulation of DNA mistakes or alterations that lead to a step-wise progression of events, ultimately resulting in cancer. These DNA alterations are typically classified as mutations, copy number changes, and gene rearrangements. Cancer also results when DNA undergoes epigenetic changes that do not involve alterations to the DNA sequence but produce modifications that result in either the silencing or activation of genes in an aberrant fashion.

CANCER IS A DISEASE OF CUMULATIVE DNA ALTERATIONS

When the balance of cell proliferation as compared with cell death or quiescence is perturbed, either due to abnormally increased proliferation or to decreased cell death or stasis, the initial steps of carcinogenesis have begun. Genes that mediate cell proliferation and cell death are often the early drivers of cancer, and many of these genes are mutated or altered in diverse types of cancer.

Two broad categories of cancer genes are termed *oncogenes* and *tumor suppressor genes*. Oncogenes, which are the accelerators of cancer growth, drive abnormal cell proliferation through various mechanisms. Common oncogenes that are often mutated or altered in human cancers include *KRAS*, *BRAF*, *PIK3CA*, and *ERBB2* (HER2). The functions of oncogenes are diverse, but many mutations and alterations that occur in oncogenes constitutively activate critical growth-promoting pathways that then drive cellular proliferation. Conversely, tumor suppressor genes act as the brakes of cell growth. Their normal function is to control cell cycling by monitoring and stopping proliferation when appropriate. Any disruption in the function of tumor suppressor genes would predictably lead to a net gain in cell numbers, possibly even without additional contributions of increased cell proliferation. Examples of tumor suppressor genes commonly mutated in human cancers include *TP53*, *CDKN2A*, *CDKN2B*, and others. Most cancers have genetic alterations involving both tumor suppressor genes and oncogenes, but the types of genetic alterations and consequences for therapies can vary dramatically between different malignancies.

DNA ALTERATIONS IN ONCOGENES AND TUMOR SUPPRESSOR GENES

Given the distinct yet complementary roles of oncogenes and tumor suppressor genes, it is perhaps not surprising that certain types of genetic alterations are associated more frequently with one or the other class of genes. Activating mutations within oncogenes, for example, tend to be heterozygous (i.e., only

ABSTRACT

Cancer is a disease of DNA mutations and other alterations that promote the growth of cells at the expense of the host. In recent years, an explosion of knowledge has been realized due to massive efforts to sequence the genomes of many different human cancers. From these studies, a new understanding of cancers has emerged, leading to improved diagnostic testing and targeted therapies. In this chapter we will review the types of genes that drive cancer growth, as well as mutations and alterations that provide opportunities for therapeutic and diagnostic exploitation.

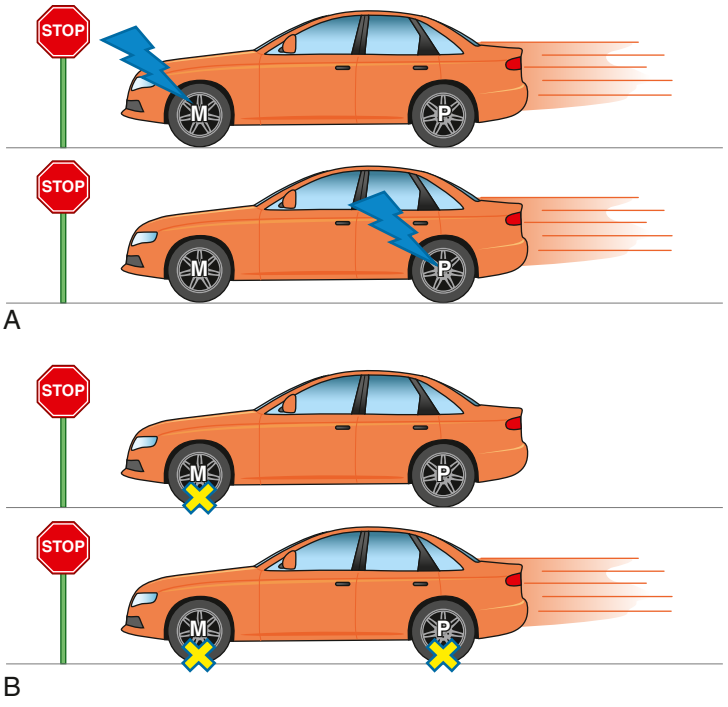

FIGURE 166-1. Oncogenes and tumor suppressor genes: the accelerators and brakes of cancer. A, Oncogenes act as the accelerators of cancer cells, driving forward even when the cell should stop (STOP sign). Oncogenic alterations such as mutations can occur in either the maternal allele (M front axle) or paternal allele (P rear axle) and will therefore cause the cell to continue to proliferate. In contrast (**B**), tumor suppressor genes are the brakes of the cell cycle. If a mutation or alteration disables only the front brakes or only the rear brakes (maternal allele; M front axle in figure), the cell can still obey stop signals. However, if both front (M axle) and rear (paternal allele; P rear axle) are disabled, the cell continues to go forward through normal stop signaling. Blue lightning bolts represent gain-of-function mutations in oncogenes; yellow X marks represent loss-of-function mutations in tumor suppressor genes.

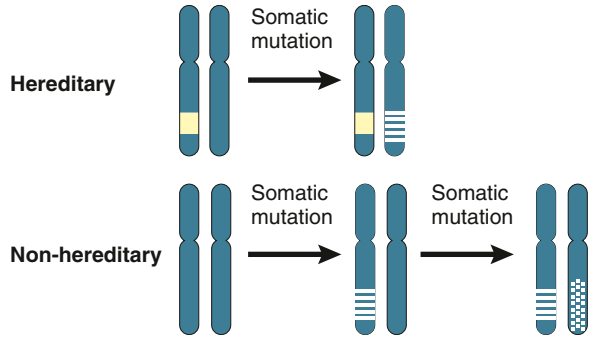

FIGURE 166-2. Knudson's two-hit model of cancer development. Biallelic inactivation (yellow band) is required for tumor initiation. In familial cancer syndromes, the first "hit" is inherited in the germline, requiring only a single somatic second "hit" (white stripes) to initiate carcinogenesis. In sporadic tumors, the first hit occurs in a single cell, and still requires the second somatic "hit" to occur in the same cell in order for tumor initiation to ensue. (Originally appearing in Jozwiak J, Jozwiak S, Wlodarski P. Possible mechanisms of disease development in tuberous sclerosis. *The Lancet Oncology*. 2008:Jan;9[1]:73-9.)

one allele is mutated) because a gain-of-function mutation would exert an effect even in the presence of the normal protein still being produced by the other wild-type allele (Fig. 166-1A). These mutations in oncogenes typically occur in regions that are known to regulate the corresponding protein's activity, such as kinase domain mutations that render the protein constitutively activated. An increased copy number of an oncogene can have a similar effect. Other examples are translocations and rearrangements, such as when the *BCR-ABL* translocation juxtaposes two genes so that the oncogene's normal function is in an "always on" state. In contrast, tumor suppressor genes generally require a loss-of-function genetic alteration, which by necessity usually requires alterations in both alleles of the cell (Fig. 166-1B). Accordingly, loss-of-function mutations observed in many tumor suppressor genes generally lead to premature truncation of the protein, such as nonsense mutations and insertion/deletion frameshift mutations. In addition, larger genomic alterations, such as deletions or loss of an entire gene or chromosome, are another mechanism for inactivating tumor suppression. Beyond these generalizations in the types of genetic alterations seen in oncogenes and tumor suppressor genes, exceptions also exist. For example, *TP53* is a tumor suppressor gene, yet the most frequent mutations found in human cancers are missense mutations, rather than frame shifts or deletions. These common missense mutations confer a dominant negative effect and prevent the p53 protein from forming tetramers, thereby usually resulting in a loss-of-function, although gain-of-function mutations in *TP53* have also been described. In contrast, certain deletions in the epidermal growth factor receptor (EGFR) gene (*ERBB1*) eliminate autoregulatory domains, thereby resulting in constitutive activation of this oncogene. Ultimately the nature and type of mutations in oncogenes and tumor suppressor genes are predicated on the domains of the protein that would readily lend themselves to activate or inactivate the gene, respectively.

GERMLINE VERSUS SOMATIC DNA ALTERATIONS IN CANCER

The human body is composed of trillions of cells, and each cell generally contains two copies (diploid) of the genome. Mature red blood cells and platelets are among the few cell types that are devoid of DNA, and gametes (i.e., ova and sperm) have only one copy of the genome (haploid), thereby allowing the zygote to inherit a haploid genome from each parent. DNA obtained from normal cells is often referred to as germline because it is derived from parental ova and sperm, which are also termed germ cells. By definition, germline DNA (sometimes also referred to as constitutional DNA) is heritable in that humans receive all their DNA from both parents. Any mutations that are present in a heterozygous fashion in germline DNA can be passed down to progeny, with a 50/50 chance of inheriting the mutant allele.

The majority of germline DNA alterations that lead to familial cancer syndromes are mutations in tumor suppressor genes.[1] In fact, the strictest genetic definition of a tumor suppressor is an alteration in a gene that predisposes to tumor formation. Indeed, pedigrees from families with hereditary predispositions to cancer have shed much light on the nature of tumor suppressor genes, including the "two-hit" hypothesis as well as the identification of key tumor suppressor genes such as *RB1, BRCA1, BRCA2* and *APC*. Since biallelic inactivation of a tumor suppressor is required to initiate cancer, familial cancer syndromes would be expected to follow an autosomal recessive pattern of inheritance. However, the majority of tumor suppressor genes are lethal to the embryo if two mutant copies are present in the zygote, so homozygosity is rarely seen in families with known mutations of a given tumor suppressor gene. Rather, a "second hit" (or inactivation of the second allele) occurs only in the cell or cells that are destined to become a tumor (Fig. 166-2). This second loss-of-function event can occur in a number of different ways, including loss of the gene, a new mutation, or epigenetic silencing. Regardless of the mechanism, because this second event occurs only in a single cell and therefore will not be present in gametes, these alterations are referred to as somatic changes. Because the human body has trillions of cells, the lifetime chance that any single cell in an individual who has inherited one mutant allele in a tumor suppressor gene will obtain a "second hit" is quite high; as a result, the pattern of inheritance for familial cancer syndromes is generally autosomal dominant. However, cancer is a result of the accumulation of many DNA alterations, so even the complete loss of function of a tumor suppressor gene is generally not sufficient to form a mass or tumor (Fig. 166-3). This requirement explains why, despite the autosomal pattern of inheritance, many familial cancer syndromes have incomplete penetrance (i.e., not all carriers will develop cancer).

Germline DNA alterations that predispose to tumor and cancer formation also explain the relatively earlier onset of diagnosis for familial cancers relative to sporadic counterparts. In the former, the initiation of cancer is accelerated because every diploid cell in the body has a lifelong functional loss of one of the two tumor suppressor genes. In the sporadic situation, by comparison, this "first hit" must occur somatically in any given cell.

With the advent of large cancer DNA sequencing, the complexity of human cancers has become apparent. Although these studies generally support the notion that most cancers arise from a stepwise accumulation of somatic genetic mutations and alterations that result in early proliferative changes, precancerous tumors, and then invasive disease, notable exceptions exist. For instance, pathogens such as viruses can initiate or predispose an individual to cancer. As an example, cells that are infected with human papillomaviruses (Chapter 344) can express proteins that inactivate key tumor suppressor genes such as p53 and RB. This suppression, which is to the advantage of the virus because cell proliferation is needed for viral replication, also establishes a situation akin

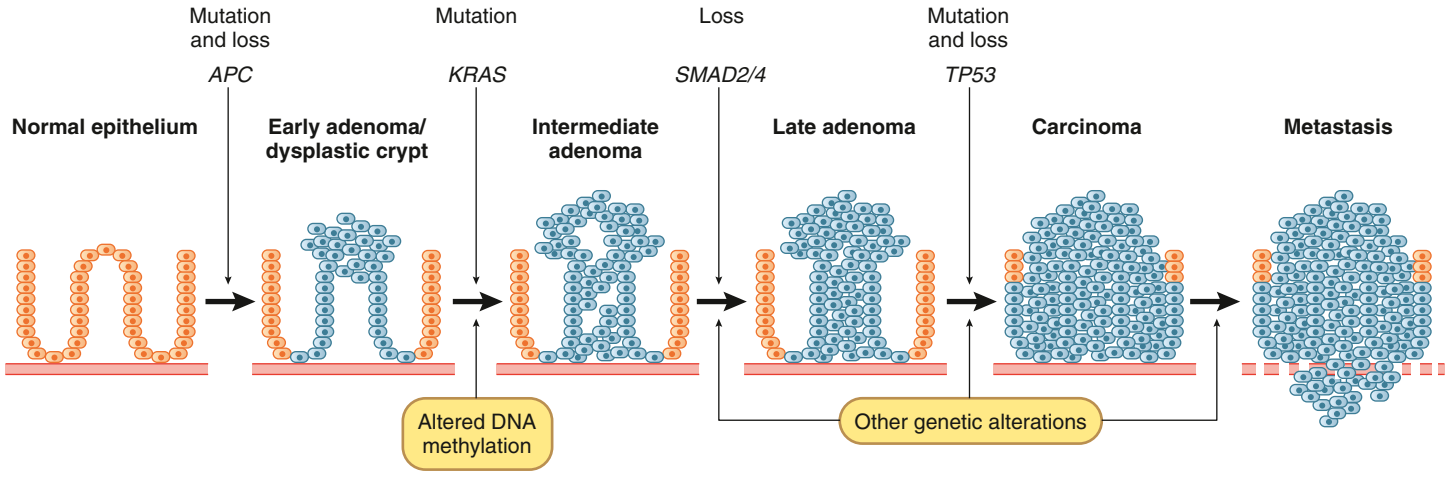

FIGURE 166-3. The stepwise progression from normal colonic epithelium to invasive cancer. Progression from normal epithelium through adenoma to colorectal carcinoma is characterized by accumulated genetic and epigenetic alterations of oncogenes and tumor suppressor genes, also known as "the Vogelgram" after Bert Vogelstein, MD. (From Davies RJ, Miller R, Coleman N. Colorectal cancer screening: prospects for molecular stool analysis. *Nature Reviews Cancer*. 2005;Mar;5[3]:199-209.)

to acquiring mutations within tumor suppressor genes. Similar to nonviral cancers, however, this suppression is an initiating event that is not sufficient to form a tumor because additional genetic events are required for a truly invasive cancer.

Sequencing studies have also shown that the number of mutations or genetic alterations required for carcinogenesis is highly variable, especially when considering the requirements for distant metastases. However, statistical analyses in pancreatic cancers suggest that two alterations may be sufficient.[2] Genomic and epidemiologic data suggest that increased cellular proliferation can be associated with an increased risk of cancer, but that the development of mutations, and therefore cancer, has a strong element of randomness or "bad luck."[3]

GENETIC INSTABILITY, CLONAL EVOLUTION, AND TUMOR HETEROGENEITY

When normal cells divide, surveillance and repair mechanisms within the cells ensure that any DNA errors are corrected prior to cytokinesis (i.e., cell division). This process ensures near-perfect fidelity and prevents the emergence of diseases, such as cancer, that are related to somatic alterations in DNA. In cancer cells, such fail-safe mechanisms are disabled, thereby allowing cells to accumulate DNA mutations, copy number changes, and genomic rearrangements. But even more daunting is that the lack of DNA repair mechanisms leads to a dynamic, ongoing process of Darwinian evolution. As cancer cells continue to divide, each resultant cell is slightly different from the next with regard to their genomes. Deleterious mutations or alterations will result in cell death, whereas advantageous changes will enable a clonal growth expansion, even as additional mutations and alterations are continually occurring within this clonal population. Although some rare cancers are exceptions to this model, modern sequencing studies of metastases support this notion, with many cancer cells within the same patient harboring so-called "private" mutations. Although some of these mutations may have no functional consequence and are therefore termed "passenger" mutations, these mutations along with other genomic alterations underscore the ongoing genetic instability of human cancers.

This continuing clonal evolution sets the stage for the development of cancer. Hallmarks (see Table 166-1) include angiogenesis, evasion of the immune system, escape from cell death and tumor suppressors, and a sustained proliferative capacity—all due to genetic alterations that directly or indirectly arise from genetic instability. Some of the mechanisms of genetic instability have been elucidated and can be classified into two broad categories. Chromosomal instability is a more common type of genetic instability in human cancers and is exemplified by copy number alterations and rearrangements. Cancers with chromosomal instability are therefore more likely to have amplifications, deletions, and aneuploidy. Conversely, genetic instability at the nucleotide level is also a much less common but well-described phenomenon, and sequencing has revealed that such cancers have thousands of mutations within their genomes and are often diploid or near diploid in contrast to tumors with chromosomal instability. This increase in mutations has been frequently referred to as high "tumor mutation burden." Several genes have been shown to mediate chromosomal instability, and many genes have also been shown to regulate an increase in tumor mutation burden. The most notable example of the latter is the mismatch repair genes and their regulation of a specific form of mutation burden termed microsatellite instability. Tumors with microsatellite instability generally have a high tumor mutation burden and a relatively diploid genome. The genetic defects that lead to microsatellite instability are the inactivation of DNA mismatch repair genes. In normal cells the presence of these mismatch repair proteins will ensure that any DNA mistakes occurring with cell replication will be corrected. The mismatch repair system is especially important for recognizing and correcting DNA mistakes that occur at base pair "repeat" sequences including mono-, di-, tri- and tetra-nucleotide sequences such as AAAAA, ATATAT, ATCATCATC, and ACGTACGTACGT, respectively. These areas of DNA repeats are scattered throughout the human genome and are termed microsatellite sequences. Tumors with microsatellite instability have difficulty repairing these microsatellite regions during DNA replication due to the lack of mismatch repair proteins. As a result, mismatch repair gene mutations, alterations, and epigenetic silencing occur in tumors with microsatellite instability. Most notably, right-sided colon cancers often have epigenetic silencing of mismatch repair proteins, with the two most frequently affected genes being *MLH1* and *MSH2*. Although not growth suppressors, *MLH1* and *MSH2* meet the definition of a tumor suppressor because germline mutations in either of these genes lead to hereditary nonpolyposis colorectal cancers and other malignancies, such as ovarian and endometrial cancers, also known as Lynch syndrome.[4] Examples of hereditary cancer risk syndromes are summarized in Table 166-2.

The genetic instability that drives tumor heterogeneity often makes cancers refractory to treatment and cure. Even though a therapeutic agent may be effective in the majority of cancer cells within a population, preexisting mutations and other alterations will then be selected as a new dominant population. In essence, the same Darwinian evolution that leads to cancer and metastases

TABLE 166-1 HALLMARKS OF CANCER

- Self-sufficiency in growth signals
- Insensitivity to anti-growth signals
- Evading apoptosis
- Limitless replicative potential
- Sustained angiogenesis

- Reprogramming energy metabolism
- Evading immune response
- Genome instability and mutation
- Tumor-promoting inflammation

Hanahan and Weinberg proposed in 2000 that there are six essential alterations in cell physiology ("hallmarks of cancer") that collectively dictate malignant growth, listed in the first six bullets. (Hanahan D, Weinberg RA. The hallmarks of cancer. *Cell*. 2000;100:57-70.) A decade later, they updated the list by adding four additional hallmarks, listed in the last four bullets. (Hanahan D, Weinberg RA. Hallmarks of cancer: the next generation. *Cell*. 2011;144:646-674.) There have been subsequent attempts to simplify the list by merging some of these core traits of most cancers. (Fouad YA, Aanel C. Revisiting the hallmarks of cancer. *Am J Cancer Res*. 2017;7:1016-1036.)

TABLE 166-2 COMMON FAMILIAL CANCER SYNDROMES

SYNDROME	GENE	ASSOCIATED TUMORS
TUMOR SUPPRESSOR MUTATIONS		
Cowden	*PTEN*	Breast, thyroid, endometrial, colorectal, kidney, melanoma
Familial adenomatous polyposis	*APC*	Colorectal, stomach, intestinal, hepatoblastoma, thyroid, pancreatic, adrenal, bile duct, medulloblastoma
Familial gastric carcinoma	*CDH1* (E-Cadherin)	Stomach, breast
Familial malignant melanoma	*CDKN2* ($p16^{INK4A}$ and $p14^{ARF}$), *CDK4*	Melanoma, pancreatic
Familial Wilms tumor	*WT1*	Wilms (kidney)
Hereditary leiomyomatosis and renal cell carcinoma	*FH*	Cutaneous leiomyomas, uterine leiomyomas (fibroids), renal cell carcinoma
Hereditary retinoblastoma	*RB1* (pRB)	Retinoblastoma
Hereditary paraganglioma	*SDHA, SDHB, SDHC, SDHD*, or *SDHAF2*(succinate dehydrogenase)	Paraganglioma, pheochromocytoma
Li-Fraumeni	*TP53* (p53)	Osteosarcoma, soft tissue sarcoma, leukemia, breast, brain, adrenal, melanoma, Wilms, stomach, colorectal, pancreatic, esophageal, lung, gonadal germ cells
Multiple endocrine neoplasia type 1	*MEN1*	Parathyroid, pituitary, islet cell, adrenal, carcinoid
Neurofibromatosis type 1	*NF1*	Neurofibroma, glioma, leukemia, breast, rhabdomyosarcoma, gastrointestinal stromal
Neurofibromatosis type 2	*NF2*	Neuromas, schwannomas, meningiomas, astrocytomas, gliomas
Peutz-Jeghers syndrome	*LKB1*	Colon, intestine, stomach, pancreas, cervix, ovary, testis, breast, thyroid
Von Hippel-Lindau	*VHL*	Kidney, adrenal, pheochromocytoma
DNA REPAIR GENE MUTATIONS		
Ataxia telangiectasia	*ATM*	Leukemia, lymphoma
Bloom	*BLM*	Leukemia, multiple solid tumors
Fanconi anemia	*FANCA, FANCC, FANCD2, FANCE, FANCF*, or *FANCG*	Leukemia, multiple solid tumors
Hereditary breast and ovarian cancer	*BRCA1* or *BRCA2*	Breast, ovary, pancreatic, fallopian tube
Lynch (hereditary nonpolyposis colon cancer)	*MLH1, MSH2, MSH6*, or *PMS2*	Colorectal, endometrial, stomach, breast, ovarian, intestinal, pancreatic, prostate, urinary tract, liver, kidney
MYH-associated polyposis	*MUTYH*	Colorectal, intestinal
Xeroderma pigmentosum	*XPA, XPC, ERCC2, ERCC3, ERCC4, ERCC5*, or *DDB2*	Skin (basal cells, squamous), melanoma, tongue, eye
ONCOGENE MUTATIONS		
Costello	*HRAS*	Papilloma, rhabdomyosarcoma, neuroblastoma
Noonan	*PTPN11, SOS1, KRAS, NRAS, RAF1*, or *BRAF* (Ras-Erk pathway regulators)	Leukemia, rhabdomyosarcoma, neuroblastoma
Familial malignant melanoma	*CDK4*	Melanoma
Multiple endocrine neoplasia type 2	*RET*	Thyroid, parathyroid, pheochromocytoma
Hereditary papillary renal cell carcinoma	*MET*	Type 1 papillary renal cell carcinoma

continues when the cancer is subjected to various chemotherapies and targeted therapies.

CANCER GENETICS AND TARGETED THERAPIES

A fundamental goal of translating genetic information about cancers is to use this knowledge for risk assessment, diagnosis, screening, and therapy. Targeted therapies are based on an understanding of how oncogenes and tumor suppressor genes drive cancer growth and then developing strategies to disrupt these mechanisms. One of the earliest examples is the *ERBB2* (HER2) oncogene and breast cancer. HER2 amplification occurs in 15 to 20% of breast cancers (Chapter 183) and is associated with an aggressive behavior and worse prognosis. The humanized monoclonal antibody, trastuzumab, was one of the first examples of a drug against a therapeutic target, because only patients with HER2 amplification/overexpression in their tumors appeared to derive benefit from this therapy. The successes of trastuzumab and additional HER2 targeted therapies (e.g., pertuzumab, neratinib, tucatinib, ado-trastuzumab, and trastuzumab deruxtecan) have changed the natural history of HER2-positive breast cancers such that they are now a highly favorable group with good prognosis (Chapter 183). This success serves as a strong reminder that understanding the underlying biology of cancer can lead to therapies that can have a dramatic impact on the disease.

Many other effective targeted therapies have shown noteworthy success (Table 166-3). Examples include imatinib, which inhibits the BCR-ABL fusion protein in chronic myelogenous leukemia (CML) (Chapter 170), thereby converting a once-fatal disease into a manageable chronic condition in which the majority of patients can now live out their natural lives.[5] In certain forms of lung cancer (Chapter 177), genomic alterations that occur with 1 to 10% frequency can be targeted with relatively specific drugs that can have a profound effect.[6]

The study of mechanisms of drug resistance has also led to an improved understanding of predictors of resistance and the development of targeted therapies that can overcome this resistance. For example, gefitinib and erlotinib are two small molecule inhibitors against certain activating mutations found within the EGFR oncogene in non–small cell lung cancers (Chapter 177). Remarkably, sequencing of tumors that developed resistance to these drugs revealed that many cancers acquired a specific recurrent mutation (i.e., T790M). Further laboratory research and clinical development led to approval of next-generation receptor tyrosine kinase inhibitors capable of overcoming cancers that harbored these mutations. Similar findings have also emerged for other diseases. As an example, accumulating evidence suggests that the emergence of resistance mutations in the estrogen receptor alpha (*ESR1*) gene's

TABLE 166-3 EXAMPLES OF TARGETED CANCER THERAPIES

THERAPEUTIC AGENT	TYPE	TARGET	DISEASE	INDICATION	COMPANION TEST
Imatinib Dasatinib Nilotinib	Small molecule	BCR-ABL	CML, ALL	Philadelphia chromosome–positive	Cytogenetic analysis, FISH, PCR
Ponatinib Bosutinib	Small molecule		CML and AML resistant to prior tyrosine kinase inhibitor therapy	Philadelphia chromosome–positive	Cytogenetic analysis, FISH, RT-PCR
Imatinib	Small molecule	c-Kit	Gastrointestinal stromal tumors	CD117 (c-Kit) positive	Immunohistochemistry (c-Kit PharmDx)
Cetuximab Panitumumab	Monoclonal antibody	EGFR	Colorectal cancer, head and neck	*KRAS* wild-type in colon cancer	PCR (*therascreen* KRAS RGQ Kit)
Gefitinib Erlotinib Afatinib Osimertinib	Small molecule	EGFR	NSCLC	Mutant EGFR	PCR (*therascreen* EGFR RGQ PCR Kit, cobas EGFR Mutation Test)
Trametinib/dabrafenib Cobimetinib/vemurafenib	Small molecule	MEK/BRAF	Melanoma	V600 mutant BRAF	PCR (THxID, cobas 4800 BRAF V600 Mutation Test)
Sotorasib	Small molecule	KRAS	Lung	G12C mutant KRAS	PCR (*therascreen* KRAS RGQ Kit) next-generation sequencing,
Trastuzumab Pertuzumab Trastuzumab emtansine (antibody drug conjugate of trastuzumab) Trastuzumab deruxtecan (antibody drug conjugate of trastuzumab)	Monoclonal antibody	HER2	Breast, stomach, gastroesophageal	HER2 positive	Immunohistochemistry (PATHWAY, InSite, Bond Oracle, HercepTest), FISH (Inform, PathVysion, SPOT-Light, HER2 CISH PharmDx)
Lapatinib Neratinib	Small molecule	HER2, EGFR	Breast	HER2 positive	HER2 testing as above
Bevacizumab	Monoclonal antibody	VEGF	NSCLC, metastatic colorectal, metastatic kidney, glioblastoma		
Ipilimumab	Monoclonal antibody	CTLA-4	Melanoma		
Pembrolizumab Nivolumab	Monoclonal antibody	PD-1	Melanoma, NSCLC, microsatellite instability–positive cancers, cancers with a high tumor mutation burden		Immunohistochemistry for PDL1, microsatellite testing, next-generation sequencing for high tumor mutation burden
Olaparib, rucaparib, talazoparib, niraparib	Small molecule	PARP1 (due to inactivation of BRCA pathway)	Breast, ovarian, prostate, pancreas	Germline and somatic *BRCA1* or *BRCA2* pathogenic variants	Next-generation sequencing of germline and/or tumor DNA

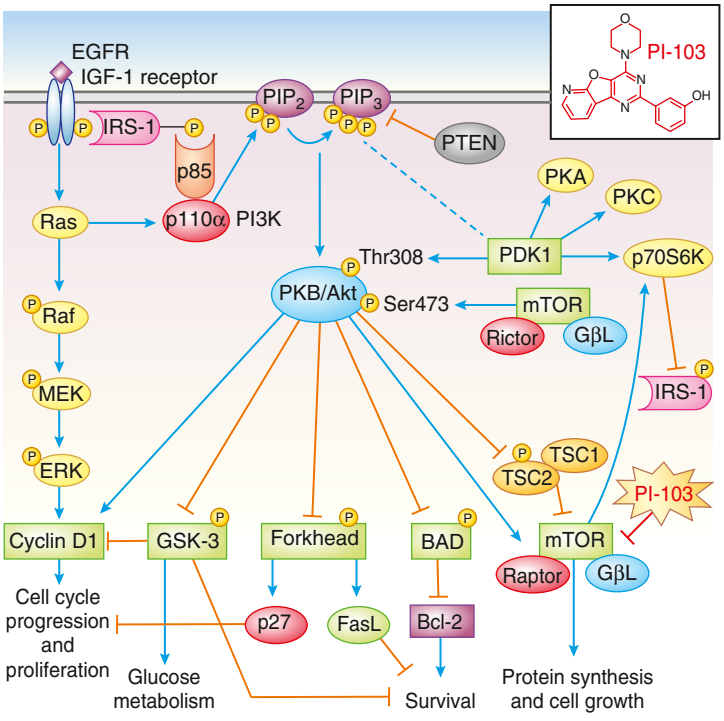
Companion tests in parentheses are U.S. Food and Drug Administration–stipulated tests for certain uses of the corresponding drug.
ALL = acute lymphoblastic leukemia; AML = acute myeloid leukemia; *BRCA1* = breast cancer gene 1; *BRCA2*; breast cancer gene 2; CML = chronic myelogenous leukemia; FISH = fluorescence in situ hybridization; NSCLC = non–small cell lung cancer; PARP = poly adenosine diphosphate-ribose polymerase; PCR = polymerase chain reaction; PDL1 = programmed death-ligand 1; RT-PCR = reverse transcription polymerase chain reaction.

ligand binding domain occur with relatively high frequency in patients whose metastatic hormone receptor-positive breast cancer (Chapter 183) is treated with aromatase inhibitors.[7] Strategies to overcome these *ESR1* mutations with newer combination endocrine therapies are being tested in clinical trials.

Although other resistance mutations have emerged through further sequencing efforts, additional clarity has been brought about with the understanding of gene mutations and their impact on signaling pathways. For example, given the sequence of events required for activation of the MAP kinase pathway (E-Fig. 166-1), it would be predicted that antibody therapies against EGFR would be ineffective in tumors that harbor an activating mutation in *KRAS*, because the activating "lesion" in this particular case is distal to EGFR. Therefore, inhibition of EGFR using a therapeutic monoclonal antibody would not yield any effect. This indeed was shown to be true and has led to the requirement for patients' tumors to be sequenced for *KRAS* prior to receiving anti-EGFR antibody therapies to ensure that only wild-type *KRAS* is present in the cancer.[8] The success and approval of mutation-specific KRAS inhibitors[9] may allow for future combination therapies.

Additional opportunities for therapeutic targeting have arisen through a better understanding of cancer genetics. "Synthetic lethality" is an idea originally based on the realization that the absence of the BRCA proteins would lead to a therapeutic vulnerability, which could be exploited because the noncancerous cells in the affected individual would still harbor 50% of a given BRCA protein due to the intact wild-type allele (Fig. 166-4). Hence, original laboratory studies demonstrated that poly adenosine diphosphate-ribose polymerase (PARP) inhibitors could effectively kill *BRCA* null cells but spare their wild-type counterparts.[10] These findings were rapidly translated into clinical trials that have led to the approval of PARP inhibitors for some ovarian (Chapter 184), breast (Chapter 183), pancreas (Chapter 180), and prostate (Chapter 186) cancers.

Although targeted therapies are generally initially approved in a single cancer tissue type, it is the target, not the particular cell type, that determines susceptibility to a targeted therapy. For example, HER2 amplified/overexpressing gastric cancers (Chapter 178) can respond to trastuzumab. Similarly, BRAF V600 oncogenic mutations generally respond to targeted



E-FIGURE 166-1. The MAP kinase and PI3 kinase/AKT signaling pathways. Shown are pathways starting from the receptor tyrosine kinase EGFR. (Adapted from Workman P, Clarke PA, Guillard S, et al. Drugging the PI3 kinome. *Nat Biotechnol*. 2006;24:794-796.)

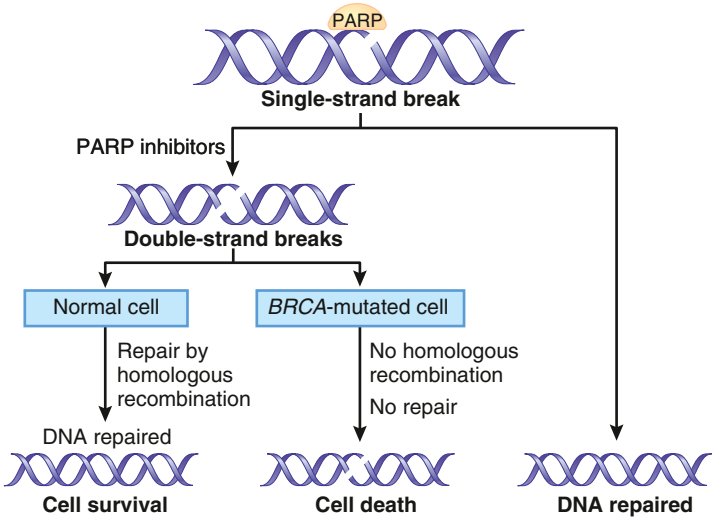


FIGURE 166-4. Poly(ADP-ribose) polymerase (PARP) inhibitors and synthetic lethality in BRCA null cells. PARP1 binds to DNA single-strand breaks that frequently occur during the cell cycle and recruits other enzymes to repair damaged DNA. Failure to repair DNA will eventually lead to further DNA damage and cell death. The BRCA pathway proteins can also repair this damaged DNA via homologous recombination. Because BRCA mediated cancers lack a BRCA protein, this ability to repair DNA via homologous recombination is lost. This is the basis for synthetic lethal and targeted therapy with PARP inhibitors in patients with BRCA-related cancers. DNA damage that occurs after inhibition of PARP activity cannot be repaired in BRCA null cancers, resulting in cell death. As BRCA proteins remain intact in noncancerous cells due to the retention of one functional copy of a *BRCA* gene, PARP inhibition selectively kills cancer cells. (From Sonnenblick A, de Azambuja E, Azim HA Jr, et al. An update on PARP inhibitors—moving to the adjuvant setting. *Nat Rev Clin Oncol*. 2015;12:27-41.)

therapies of V600 inhibitors, although colorectal cancers seem to be a notable exception.[11] Interestingly, suppression with BRAF V600 mutant inhibitors can lead to dysregulation of feedback networks in normal and cancerous cells. Combination therapies, including inhibitors of MEK, which is a molecule distal to BRAF in the MAP kinase pathway (E-Fig. 166-1), result in more efficacious therapy with fewer side effects. Another example of molecular targeted therapies is larotrectinib, which is an inhibitor of TRK proteins that have been made constitutively active via translocation of *TRK* genes with other genes, also known as fusion partners. This potent inhibitor has striking antineoplastic activity against a variety of tumor types, provided they have either a *TRK1*, *TRK2*, or *TRK3* translocation that leads to constitutive activation.[12] Both larotrectinib and entrectinib, which is another *TRK* inhibitor, are now FDA-approved for responsive cancer.

Research also led to the first approved antineoplastic therapy based upon the type of genetic instability. Melanomas and squamous cell lung cancers with high mutation burden are more likely to respond to immune check point inhibitors, in part because ultraviolet light and tobacco exposure, respectively, led to their high mutation burdens. Cancers with a high tumor mutation burden imparted by microsatellite instability have a significantly higher response rate to immune checkpoint inhibitor therapies, often even if such tumors have become refractory to all other therapies.[13]

CANCER GENETICS FOR DIAGNOSTICS

GENE EXPRESSION PROFILING FOR PROGNOSIS AND PREDICTION

The majority of RNA prognostic and predictive tests do not measure DNA alterations but instead assess relative levels of RNA within a tumor. These RNA levels are then used for various algorithms that have been validated for both prognostic information (i.e., the likelihood of recurrence and/or survival over a defined time frame) as well as predictive power (i.e., the likelihood of a patient benefitting from a given therapy). Several such tests have been validated in prospective trials[14] to help inform clinical decisions.

DIAGNOSTIC TESTS FOR TARGETED THERAPIES

Targeted therapies require genetic testing to select patients who will have the highest likelihood of responding to a given agent. For example, early studies of trastuzumab would likely have failed had patients not been preselected for HER2 amplification, given that the majority of breast cancers are HER2 negative. Next-generation sequencing (also see Chapter 33) involves generation of DNA "libraries" that are sequenced simultaneously (i.e., massively and in parallel), thereby generating terabytes or more of data. Redundant sequencing is needed to ensure that each nucleotide is sequenced enough times to differentiate true mutations from artifacts of the next-generation sequencing process. Each DNA molecule that is sequenced is then aligned against a reference genome to determine the presence or absence of mutations.

Because reference genomes are derived from a variety of sources, it is not always possible to distinguish a mutation from a normal variant that could exist within the population. As such, "germline sequencing and filtering" is becoming more commonplace for tumor sequencing. This technique entails obtaining a normal DNA sample from the patient whose tumor is being sequenced and subjecting the normal germline DNA to next-generation sequencing. After sequencing and alignment, the germline DNA is electronically subtracted from the tumor DNA to reveal only somatic mutations. Although this process can reduce the number of false-positive mutations, it also can potentially filter out important germline mutations that may have therapeutic relevance for a given cancer (e.g., *BRCA1*, *BRCA2*, *MLH1*, and *MSH2*). Newer bioinformatic methods may circumvent these issues by either not filtering germline mutations in key genes or identifying the likelihood of somatic versus germline mutations with the use of statistical algorithms.

Ongoing clinical trials are trying to exploit cancer DNA as a general diagnostic screening tool. For example, multitarget analysis of stool specimens using mutation testing, epigenetic markers, and a hemoglobin immunoassay has a relatively high sensitivity and specificity for detecting early-stage colorectal cancers,[15] and is now FDA-approved for colorectal cancer screening.

Next-generation sequencing has also brought to reality the concept of a "liquid biopsy," which is testing for circulating cell-free DNA for cancer diagnostics. All cells, cancerous and normal, shed DNA into the circulation.[16] This cell-free DNA can be isolated and analyzed by next-generation sequencing for a variety of purposes including identifying circulating tumor DNA using various substrates such as plasma, serum, urine, saliva, and others.[17,18] Next-generation sequencing, polymerase chain reaction testing, and other technologies have now become commonplace for detecting tumor mutations in the circulation.[19] Cell-free DNA is also being studied as a marker for residual cancer burden, response to therapies, and prognosis. In addition, asymptomatic clonal hematopoiesis, whereby precancerous stem cells accumulate genetic mutations that increase the risk of malignant transformation,[20] is another potential marker of prognosis. Interventions based on these new technologies have the potential to revolutionize how patients are treated for both early- and late-stage cancers, thereby allowing for precise knowledge of whether therapies are truly eradicating microscopic residual disease and effecting cures.

167 MYELODYSPLASTIC SYNDROMES

RICHARD M. STONE

DEFINITION

The myelodysplastic syndromes include a heterogeneous group of bone marrow failure syndromes collectively characterized by ineffective hematopoiesis that results in peripheral blood cytopenias, most commonly anemia.[1] In some patients, the distinction between myelodysplastic syndrome and acute myeloid leukemia (AML; Chapter 168) may be challenging.[2] Although the dominant clinical feature of myelodysplastic syndromes is bone marrow failure, myelodysplastic syndromes are clonal disorders and therefore classified as hematopoietic neoplasms by the World Health Organization (WHO) and other organizations.

EPIDEMIOLOGY

The incidence and prevalence of myelodysplastic syndromes have been difficult to estimate accurately, in part because of varying definitions and

ABSTRACT

The myelodysplastic syndromes include a group of clonal hematopoietic stem cell disorders defined by marrow failure, dysplastic cell morphology, and a risk of clonal evolution including to acute myeloid leukemia (AML). Most cases arise de novo, but 10 to 20% are a consequence of prior cytotoxic chemotherapy or radiation therapy, and myelodysplastic syndromes due to a germline predisposition are increasingly recognized. More than 40 genes are recurrently mutated in association with myelodysplastic syndromes, including genes encoding factors important in epigenetic patterning, chromatin remodeling, mRNA splicing, signal transduction, transcription, and DNA repair. More than one half of patients have cytogenetic abnormalities in marrow cells, usually aneuploidy such as monosomy 7 or trisomy 8, or a deletion of the long arm of chromosomes 5 or 20. The most widely used myelodysplastic syndrome classification system is the 2016 World Health Organization criteria. Because the natural history of myelodysplastic syndromes is highly variable, risk stratification using tools such as the 2022 Molecular International Prognostic Scoring system is important for counseling patients and choosing appropriate therapy. Only allogeneic hematopoietic cell transplantation offers the possibility of cure, but most patients with myelodysplastic syndromes are not transplant candidates due to advanced age and comorbid conditions. Approved disease-modifying therapies include azacitidine, decitabine, decitabine/cedazuridine, and lenalidomide. Supportive care with erythropoiesis-stimulating agents, luspatercept, transfusions, and iron chelation are important for some patients. Enrollment in clinical trials is essential given the poor outcomes, especially patients who have been failed by hypomethylating agents.

imprecise terminology historically, and also because myelodysplastic syndrome cases are incompletely captured by cancer registries. About 10,000 to 12,000 new cases are officially diagnosed each year, but analysis of Medicare claims suggests that the actual incidence of myelodysplastic syndromes is much higher, with at least 40,000 new U.S. cases per year—more than twice the incidence of AML. In addition, many geriatric patients have mild cytopenias and may have myelodysplastic syndromes that have been incompletely evaluated (e.g., they do not undergo bone marrow aspiration) and never are specifically diagnosed.

The primary risk factor for development of a myelodysplastic syndrome is aging, with disease resulting as a consequence of cumulative acquisition of somatic mutations in marrow stem cells. In Asia and Eastern Europe, a myelodysplastic syndrome is typically diagnosed at younger ages than in the West; in the United States, the median age at which myelodysplastic syndromes are diagnosed is about 71 years, whereas in China it is closer to 50 years. Overall, males are slightly more affected than females.

The rate at which myelodysplastic syndromes are diagnosed is slightly increased in workers in certain industries such as the petroleum industry and agricultural sector, probably because of exposure to agents that favor expansion of mutant clones. Individuals who have been exposed to ionizing radiation or to certain types of cytotoxic chemotherapy (i.e., alkylating agents such as chlorambucil or melphalan, or topoisomerase II inhibitors such as etoposide or doxorubicin) have an increased risk for developing myelodysplastic syndromes. The peak incidence at which a myelodysplastic syndrome is diagnosed after exposure to an alkylating agent or radiation is 5 to 10 years later, whereas it is 1 to 3 years after exposure to a topoisomerase inhibitor. This increased risk never completely disappears; even 50 years after the Hiroshima and Nagasaki atomic bomb events in Japan, radiation-exposed individuals continued to be diagnosed with myelodysplastic syndromes at a higher rate than the unexposed population. Patients with a chemotherapy or radiation exposure history are said to have therapy-related myelodysplastic syndromes.

PATHOBIOLOGY

Myelodysplastic syndromes are clonal disorders, by which it is meant that one or several stem or progenitor cells in the marrow that bear somatic gene mutations proliferate at the expense of healthy stem cells, and these mutation-bearing progeny eventually come to dominate the bone marrow. Clones can acquire additional mutations that give rise to subclones, which can contribute to progression of disease if they have a greater proliferation potential than the original mutant clone. The process of somatic mutation acquisition may be accelerated through exposure to radiation or DNA-damaging chemicals, but more important, such exposures can also select for small *TP53* or *PPM1D* mutant preexisting clones. The marrow microenvironment (i.e., nonhematopoietic stromal cells) appears to play an important role in supporting neoplastic clones.

Marrow cellularity is usually normal or increased in myelodysplastic syndromes, but excessive apoptosis (i.e., programmed cell death) of hematopoietic cells within the bone marrow accounts for the peripheral blood cytopenias. Although excessive apoptosis within the marrow characterizes earlier phases of myelodysplastic syndromes, as the disease progresses toward AML, intramedullary apoptosis may decrease. In addition, hematopoietic differentiation, which is disordered but still can proceed in earlier stages of the disease, may become completely impaired later in the disease course such that most developing hematopoietic cells are arrested at the myeloblast stage.

Large gains and losses of chromosomal material within the disease cells, detectable by routine metaphase karyotyping, are present in one half of patients with de novo myelodysplastic syndromes and in more than 80% of patients with therapy-related myelodysplastic syndromes. Genetic techniques such as array-based comparative genomic hybridization can uncover cryptic chromosomal deletions in some patients whose myelodysplastic syndromes are associated with normal karyotyping results.

More than 40 genes are now known to be recurrently mutated in myelodysplastic syndromes,[3] but most of these mutations are also commonly detected in AML and other myeloid neoplasms, albeit at different frequencies.[4] No single mutation dominates; myelodysplastic syndromes are associated with considerable genetic heterogeneity (Table 167-1). More than 90% of patients with myelodysplastic syndromes have at least one detectable clonal somatic mutation, which influences the clinical presentation and prognosis. Mutations affecting epigenetic patterning through DNA methylation and chromatin conformation (e.g., histone-DNA interactions) are common.[5] In addition, mutations affecting pre-mRNA splicing are frequent,[6] especially in patients with ring sideroblasts (i.e., erythroid precursors with abnormal perinuclear iron-containing mitochondria visible with Perls Prussian blue reaction) (see Fig. 167-1C); the specific genes that are mis-spliced and give rise to a myelodysplastic syndrome phenotype are as yet unclear.

Genetic bone marrow failure syndromes such as Schwachman-Diamond and Fanconi anemia (Chapter 151) are associated with myelodysplastic syndrome in children.[7] Up to 20% of adults with myelodysplastic syndrome may have a germline predisposition, and inherited forms of myelodysplastic syndrome, such as Schwachman-Diamond, may present in the sixth decade of life or later.

A subset of patients with pathologic findings that resemble a myelodysplastic syndrome will have autoimmune hematopoietic suppression, which may be driven by an expanded autoreactive T-lymphocyte population. Patients are more likely to have an immune component to their marrow failure if they are younger than 55 years and have a hypocellular marrow similar to what is seen in aplastic anemia, a normal chromosome pattern or trisomy 8 (rather than a more complex karyotype), a paroxysmal nocturnal hemoglobinuria cell population detectable by flow cytometry (Chapter 146), and HLA DR15 tissue type. Such patients may respond to immunosuppressive anti-T-cell therapies.

CLINICAL MANIFESTATIONS

Most patients with myelodysplastic syndromes come to medical attention because they have anemia. Anemia is present in 95% cases and is often macrocytic, but about 50% of patients also have neutropenia, thrombocytopenia, or both at the time of diagnosis.

The clinical course in myelodysplastic syndromes is dominated by complications of the cytopenias, including mucosal bleeding, recurrent infections, and exertional dyspnea and fatigue. Fatigue correlates poorly with the degree of anemia and may be in part due to cytokine release by the abnormal clonal cells. Paraneoplastic manifestations, including neutrophilic dermatosis (Sweet syndrome, Chapters 406 and 407), inflammatory arthritis, and other rheumatologic syndromes, occur in 10 to 15% of patients. Repeated transfusions of red cells can lead to transfusional hemosiderosis and organ dysfunction, including hepatic and cardiac disease. The frequency with which complications of iron overload occur, as well as the importance of chelation therapy in myelodysplastic syndromes, are controversial topics.[8]

DIAGNOSIS

Myelodysplastic syndromes are usually suspected when an older patient is discovered to have cytopenias, especially macrocytic anemia that is not due to B_{12} or folate deficiency, medication effect (e.g., methotrexate or azathioprine), or alcohol abuse. The blood count abnormality may be an incidental finding, but most patients with myelodysplastic syndromes are symptomatic with fatigue, dyspnea, and other cytopenia-associated symptoms.

The peripheral blood exhibits characteristic "dysplastic" cell morphologic abnormalities. In the peripheral blood, these abnormalities include hypogranular neutrophils, hypolobated neutrophils such as the two-lobed pseudo-Pelger-Hüet cell (Fig. 143-20), increased platelet size and platelet hypogranularity, poorly hemoglobinized red cells, and circulating early myeloid cells including a small number of myeloblasts (Chapter 143).

A bone marrow aspirate is required to make the diagnosis, and bone marrow core (trephine) biopsy is also useful and can provide information about the marrow architecture and overall marrow cellularity.[9] Maturation abnormalities in the bone marrow include megaloblastoid erythroid changes, multinucleated erythroid cells, ring sideroblasts, nuclear karyorrhexis, left-shifted myelopoiesis, hypogranular white cells, micromegakaryocytes, large hypernucleated megakaryocytes, or hypolobated megakaryocytes (Fig. 167-1). A mild increase in reticulin fibrosis is common in myelodysplastic syndromes, but severe reticulin fibrosis and collagen fibrosis are rare. Extramedullary hematopoiesis is uncommon in myelodysplastic syndromes, and the presence of splenomegaly or hepatomegaly should prompt consideration of another diagnosis. Metaphase cytogenetics is essential, whereas fluorescence in situ hybridization (FISH) is only necessary if karyotyping fails because of unsuccessful marrow aspiration. FISH abnormalities are rarely detected in patients for whom at least 20 metaphases can be counted during karyotyping. Flow cytometric immunophenotyping can provide useful diagnostic and prognostic information but should not be relied on to count blast proportion.

Although not technically required to make the diagnosis, a next generation sequencing panel can provide adjunctive diagnostic information. Genetic-clinical correlations including a thrombocytopenic prodrome in RUNX1 mutant patients and the association of GATA2 mutations with mycobacterial infections, warts, or monocytopenia. Patients with a *TP53* mutation may warrant identification because of their poorer prognosis.[10]

TABLE 167-1 GENE MUTATIONS ASSOCIATED WITH MYELODYSPLASTIC SYNDROMES AND FUNCTIONAL CLASS OF THE ASSOCIATED PROTEIN

RECURRENTLY MUTATED GENES	MUTATION FREQUENCY IN MDS	ADDITIONAL NOTES
SPLICEOSOME COMPONENTS (ALTER PRE-mRNA SPLICING)		
SF3B1	20-25%	Strongly associated with the presence of ring sideroblasts (60-80% of MDS-RS cases), often co-occurs with *DNMT3A* mutations; associated with more favorable outlook
U2AF1	5-10%	Often co-occurs with del(20q)
SRSF2	5-10%	More frequent in CMML (25-30%) than in MDS without proliferative features, often co-occurs with *RUNX1* or *ASXL1* mutations
ZRSR2	3-5%	
U2AF2, SFRA1, PRPF40B, SF1	<2% each	
EPIGENETIC PATTERN AND CHROMATIN CONFORMATION MODIFIERS		
TET2	20-25%	More frequent in CMML (~40%)
DNMT3A	10-15%	Low variant allele frequency mutations are also commonly found in the healthy elderly population
SETBP1	5-10%	More common in CMML; associated with adverse prognosis in that setting
ASXL1	10-20%	More frequent in CMML (~40%)
**EZH2*	6%	More frequent in CMML (~12%)
KDM6A	<2%	Rare in MDS, more frequent in CMML
IDH1, IDH2	<2%	More frequent in AML than MDS; amenable to targeted therapy with novel agents
PHF6	<1%	
ATRX	Rare	Associated with acquired α-thalassemia (hemoglobin H inclusions in red blood cells)
TRANSCRIPTION FACTORS/DNA REPAIR		
**RUNX1*	10-15%	Germline mutations cause Familial Platelet Disorder with propensity to AML (FPD-AML)
ETV6	<5%	Translocations common in AML; formerly known as *TEL*
MYBL2	<1%	
GATA2	Rare	Germline mutations cause familial MDS with monocytopenia
CEBPA	Rare	More frequently mutated in AML, germline mutations cause familial AML without preceding dysplasia
WT1	Rare	More frequently mutated in AML
**TP53*	5-10%	Associated with very poor prognosis; associated with t-MDS and with complex karyotype
TYROSINE KINASE SIGNALING		As a group, these genes are more often mutated in myeloid malignancies with a proliferative component
NRAS, KRAS, BRAF	5-10% collectively	*NRAS* mutations more common in CMML and AML; first mutations described in MDS (1987)
JAK2	<5%	More frequent in MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T) (50%)
CBL, CBLB	<5%	More frequently mutated in CMML than MDS
FLT3, MPL, KIT	<1%	*MPL* mutated in (5%) of MDS/MPN-RS-T; *FLT3* and *KIT* mutations are rare in MDS and much more common in AML
NF1	<1%	Germline mutations cause neurofibromatosis type 1
PTPN11	<1%	Rare in MDS, more frequent in JMML (30%)
OTHERS		
NPM1	<2%	Much more frequently mutated in AML
GNAS	<1%	
BCOR, BCORL1	<1%	More common in aplastic anemia
PIGA	<1%	Associated with a *PNH* clone; more common in paroxysmal nocturnal hemoglobinuria
UMODL1	<1%	
ZSWIM4	<1%	
PPM1D	1-3%	Associated with t-MDS
Cohesins *(RAD21, STAG1, STAG2, SMC3, SMC1A)*	5-10%	Despite role in chromatid segregation, not associated with numerical chromosome abnormalities

*Mutations that appear to be independently associated with poor outcomes in myelodysplastic syndromes (MDS).

AML = acute myeloid leukemia; CMML = chronic myelomonocytic leukemia; JMML = juvenile myelomonocytic leukemia; MDS = myelodysplastic syndromes; MDS-RS = MDS with ringed sideroblasts; MDS/MPN-RS-T = MDS/myeloproliferative neoplasm overlap syndrome with ring sideroblasts and thrombocytosis; pre-mRNA = precursor-messenger RNA; t-MDS = therapy-related myelodysplastic syndrome.

Diagnostic Criteria

Minimal diagnostic criteria for a myelodysplastic syndrome include the presence of one or more cytopenias, together with at least one additional feature. These features include: 5 to 19% marrow myeloblasts (although patients who have 10 to 19% marrow blasts may be classified as having myelodysplastic syndrome/acute myeloid leukemia);[11] an abnormal marrow karyotype with an acquired chromosome anomaly that is consistent with the diagnosis of a myelodysplastic syndrome;[12] or greater than 10% cells in any given hematopoietic linage that appears dysplastic (i.e., morphologically abnormal) in a patient in whom other causes of dysplastic cell morphology, such as nutritional deficiency or a drug effect, have been excluded.

Differential Diagnosis

Specific Other Diagnoses

Dysplastic hematopoiesis has a broad differential diagnosis, and other potential causes for cytopenias and morphologic abnormalities must be considered. This differential diagnosis includes nonclonal disorders such as B_{12} or folate deficiency (Chapter 150), copper deficiency (especially if ring sideroblasts are present), iron deficiency (Chapter 145), HIV infection, medication exposure (especially cytotoxic chemotherapy agents), or an immune disorder such as T-cell large granular lymphocyte (T-LGL) leukemia. In patients with isolated sideroblastic anemia (Chapter 145), it is important to exclude congenital sideroblastic anemias, including those due to germline mutations in *ALAS2*, which can present late in life.

Myelodysplastic syndromes must be distinguished from aplastic anemia (Chapter 151), which can be oligoclonal and associated with some of the same somatic mutations as myelodysplastic syndromes, but which is not typically associated with Pelger-Hüet cells or other morphologic abnormalities. The karyotype in aplastic anemia is usually (but not always) normal. Myelodysplastic syndromes can also be mistaken for a myeloproliferative neoplasm such as primary myelofibrosis (Chapter 152). Cases in which myelodysplastic syndrome features, such as cytopenias, overlap with myeloproliferative neoplasm features, such as leukocytosis and splenomegaly, include chronic myelomonocytic leukemia, which requires >1000 monocytes/μL in the blood to diagnose. The WHO categorizes myelodysplastic syndrome/myeloproliferative neoplasm overlap syndromes separately from myelodysplastic syndromes, and these cases have a distinct mutational spectrum.

Variants of Myelodysplastic Syndrome

Some patients with persistent cytopenias do not meet diagnostic criteria for a myelodysplastic syndrome, but no other diagnosis is apparent, even after detailed investigation.[13] This pattern has been termed *idiopathic cytopenias of undetermined significance* if a clonal somatic mutation is absent and *clonal cytopenias of undetermined significance* if a somatic myelodysplastic syndrome-associated mutation (e.g., *DNMT3A, TET2*) is present. Such patients should be followed over time because they have a risk for developing an overt myelodysplastic syndrome, especially if they have a clonal cytopenia of undetermined significance. More than 10% of the healthy population age 70 years or older have a somatic mutation in *DNMT3A, TET2*, or another myelodysplastic syndrome-associated gene; therefore, identification of a clonal mutation in the absence of any myelodysplastic syndrome feature (called *clonal hematopoiesis of indeterminate potential*) is not considered diagnostic of a myelodysplastic syndrome. If a patient has cytopenias even in the absence of characteristic myelodysplastic syndrome-associated morphologic abnormalities and a typical myelodysplastic syndrome-associated marrow cytogenetic abnormality (e.g., loss of chromosome 7 or deletion of the long arm of chromosome 5), the patient can be considered to have "unclassifiable

myelodysplastic syndrome" (Table 167-2). Patients with clonal hematopoiesis of indeterminate potential (Chapter 142) have an increased risk for developing a myelodysplastic syndrome or another hematologic malignancy, and they also have an increased risk for cardiovascular mortality.[14]

TREATMENT

Given the heterogeneity of myelodysplastic syndromes and the wide spectrum of functional status and comorbid conditions among patients with myelodysplastic syndromes, treatment must be individualized.[15–17] Currently, lack of a specific well-characterized molecular target in most patients with myelodysplastic syndromes precludes a true biologically based approach to therapy. Algorithms for treatment (Fig. 167-2) are based primarily on the patient's prognosis.

General Approach to the Patient

When choosing a potential therapy for a patient with a myelodysplastic syndrome, clinicians should consider the patient's age,[18] comorbid conditions, functional status, disease biology, and disease kinetics. Some patients with myelodysplastic syndromes have mild cytopenias and minimal or no symptoms, and they can reasonably be observed without therapy. For higher-risk patients (e.g., revised International Prognostic Scoring System high or very high risk [Fig. 167-3]), immediate therapy is usually indicated because such patients are usually severely cytopenic and have a life expectancy of less than 2 years. For lower-risk patients (very low risk or low risk on the revised International Prognostic Scoring System or the Molecular International Prognostic Scoring System [https://mds-risk-model.com]), a more cautious approach is appropriate.

The only curative modality for a myelodysplastic syndrome is allogeneic hematopoietic stem cell transplantation (Chapter 163), so this option should be considered in developing a therapeutic plan if the patient is young enough and lacks other major medical problems. If transplantation is not the goal, prolonged administration of hypomethylating agents is generally indicated. In lower-risk patients who have a chromosome 5 abnormality, the immunomodulatory agent lenalidomide is the treatment of choice. For other lower-risk patients, supportive care alone, hematopoietic growth factors, immunosuppressive therapy, immunomodulatory therapy, or hypomethylating agents can be considered, depending on the clinical situation.

Stem Cell Transplantation

Allogeneic hematopoietic stem cell transplantation (Chapter 163) should be considered promptly and generally be performed if feasible in all patients who have higher-risk myelodysplastic syndromes, who are approximately age 75 years or younger, and who lack major comorbid conditions. Allogeneic transplantation also may lead to better outcomes than medical therapy alone in higher-risk patients age 55 years or older.[19–21] The optimal conditioning regimen is unclear.[A1] Reduced-intensity conditioning stem cell transplantation is feasible in adults up to age 75 years, whereas myelosuppressive stem cell transplantation is generally reserved for patients younger than age 55 years.

Because most patients with myelodysplastic syndromes are older and uncommonly have a younger sibling who is a suitable stem cell donor, azacitidine or decitabine (see DNA Hypomethylating Agents) may be useful to stabilize a patient before transplantation while the search for an unrelated donor is ongoing.

The long-term outcome of patients undergoing stem cell transplantation varies widely according to disease and host features. Treatment-related mortality is as high as a 15 to 20% risk. Relapses are unfortunately common, but approximately 40% of patients will become long-term disease-free survivors.

Supportive Care

Hematopoietic Growth Factors and Other Approaches to Cytopenias

Because most patients with myelodysplastic syndromes are anemic, the erythropoiesis-stimulating agents epoetin and darbepoetin[A2] are often used under expert supervision, even though these agents are not specifically approved by the U.S. Food and Drug Administration (FDA) for treatment of myelodysplastic syndromes. The benefits of erythropoiesis-stimulating agents are generally modest and of limited duration. Patients with lower baseline serum erythropoietin levels (<500 U/L, and especially <100 U/L) are more likely to respond to erythropoiesis-stimulating agents than are patients with higher baseline serum erythropoietin levels. For patients with ring sideroblasts, the addition of low-dose granulocyte colony-stimulating factor (G-CSF) to the erythropoiesis-stimulating agent may potentiate the erythropoietic response.

In patients who have lower-risk myelodysplastic syndromes (>15% ring sideroblasts, or >5% ringed sideroblasts and an SF3B1 mutation) and who have high erythropoietin levels or have become refractory to or intolerant of

TABLE 167-2 WORLD HEALTH ORGANIZATION SUBTYPES OF MYELODYSPLASTIC SYNDROME (MDS)

MDS SUBTYPE	DYSPLASIA	BLAST COUNT	OTHER FINDINGS
MDS with single-lineage dysplasia (MDS-SLD)	• Present in only 1 lineage (>10% of cells in that lineage)	• Peripheral blood: <1% • Bone marrow: <5%	• Cases with bilineage cytopenias may be included in this category, but marrow dysplasia must be limited to 1 lineage • Ring sideroblasts represent <15% of erythroid precursors
MDS with ring sideroblasts (MDS-RS)	• Present in the erythroid lineage (>10% of erythroid precursors); subtypes with single-lineage dysplasia (MDS-RS-SLD) and with multilineage dysplasia (MDS-RS-MLD)	• Peripheral blood: none • Bone marrow: <5%	• Anemia (normocytic/macrocytic) • Ring sideroblasts comprise ≥15% of erythroid precursors or if *SF3B1* mutation is present ≥5% of erythroid precursors
MDS with multilineage dysplasia (MDS-MLD)	• Present in 2 or more lineages (>10% of cells in each affected lineage)	• Peripheral blood: <1% • Bone marrow: <5%	• One or more cytopenias • No Auer rods • If ≥15% of erythroid precursors or if *SF3B1* mutation is present in ≥5% of erythroid precursors, represents MDS-RS-MLD
MDS with excess blasts-1 (MDS-EB-1)	• Present in 1 or more lineages (>10% of cells in each affected lineage)	• Peripheral blood: <5% • Bone marrow: 5-9%	• One or more cytopenias • No Auer rods • 2-4% blasts in the peripheral blood → MDS-EB-1
MDS with excess blasts-2 (MDS-EB-2)	• Present in 1 or more lineages (>10% of cells in each affected lineage)	• Peripheral blood: 5-19% • Bone marrow: 10-19%	• One or more cytopenias • The presence of Auer rods for any blast count <20% → MDS-EB-2
MDS with isolated deletion of chromosome 5q (5q− syndrome)	• Increased numbers of megakaryocytes, many small and with hypolobated/nonlobated nuclei • Minimal or no dysplasia in granulocytic lineage	• Peripheral blood: no or rare blasts (<1%) • Bone marrow: <5%	• Anemia (often macrocytic) with or without other cytopenias/thrombocytosis • No Auer rods • Interstitial or terminal deletion of the long arm of chromosome 5 with no or one other cytogenetic abnormality
MDS, unclassifiable	• Unequivocal, but present in <10% of cells of one or more lineages	• Peripheral blood: ≤1% • Bone marrow: <5%	• May progress to a specific MDS • Can also include cases otherwise classified as: MDS-SLD or MDS-MLD but with 1% blasts in peripheral blood; MDS-SLD but with pancytopenia • Cases with an MDS-associated chromosome abnormality (other than loss of the Y chromosome or trisomy 8 or deletion of chromosome 20) but without dysplasia can be included in this category

Data based on the 2016 WHO classification of hematopoietic and lymphoid neoplasms (Arber D, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood* 2016:127:2391-2405), which was a minor revision of the 2008 classification. Familial myeloid neoplasms are classified separately, as are therapy-related myeloid neoplasia and myelodysplastic syndromes with myeloproliferative neoplasm features.

- Consider clinical trial enrollment for all patients
- Supportive care (e.g., transfusions and antimicrobials as needed) for all patients; consider chelation
- Risk stratification using the Revised International Prognostic Scoring System (see Table 167-2) supplemented by molecular testing

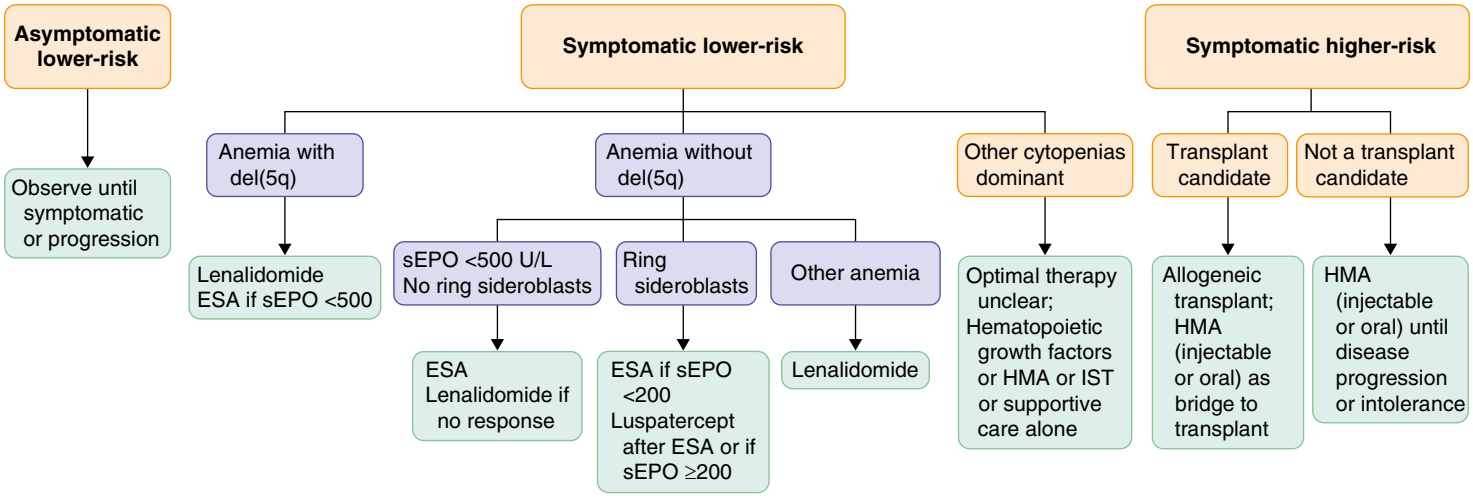

FIGURE 167-2. Treatment algorithm in myelodysplastic syndromes. EPO = erythropoietin; ESA = erythropoiesis-stimulating agent; HMA = DNA hypomethylating agent; IST = immunosuppressive therapy; sEPO = serum erythropoietin level. (Adapted from Steensma DP. Myelodysplastic syndromes current treatment algorithm 2018. *Blood Cancer J*. 2018;8:1-7.)

erythropoiesis-stimulating agents, luspatercept (1.0 to 1.75 mg/kg subcutaneously every 3 weeks) can reduce the severity of anemia by binding to cytokines that have a negative effect on erythropoiesis.[A3] A few patients will benefit from treatment with androgens, but the risk for prostate enlargement (in men) and other complications such as hepatotoxicity must be considered.

Myeloid growth factors such as G-CSF can ameliorate the neutropenia often seen in myelodysplastic syndrome patients but is not likely to reduce the risk for infections or provide other clinical benefits because of the frequency of neutrophil dysfunction in addition to neutropenia. Prophylactic antimicrobial agents have no clear role, but they can be considered in patients who have experienced recurrent infections or are at particularly high risk.

The thrombopoiesis-stimulating agents romiplostim and eltrombopag are not approved by the FDA for myelodysplastic syndromes and may induce progression to AML in some patients, but they may be useful in patients who have severe thrombocytopenia or clinically significant bleeding.[A4] Platelet transfusions should be used carefully in myelodysplastic syndrome patients because of the risk for alloimmunization. Prophylactic transfusion is appropriate only in patients with platelet counts less than 10,000/μL. Patients with mucosal bleeding and refractory thrombocytopenia may benefit from treatment with antifibrinolytic agents such as aminocaproic acid under expert supervision.

Iron Chelation Therapy

The multiple red blood cell (RBC) transfusions needed by some patients with myelodysplastic syndromes may cause iron overload and tissue injury, but the frequency with which this complication occurs is unclear. Furthermore, the toxicity and high cost of available chelators (e.g., deferasirox, deferiprone, or deferoxamine) makes their use controversial. A trial of iron chelation therapy is reasonable in patients with lower-risk disease and high transfusional burdens (e.g., more than 20 to 40 RBC units transfused).[A5]

Disease-Modifying Medical Therapy

DNA Hypomethylating Agents

Azacitidine and decitabine are two azanucleoside analogues that inhibit the enzyme DNA methyltransferase, thereby altering the cytosine methylation "epigenetic" status of DNA and changing gene expression. These agents have become the mainstay of therapy for most patients with higher-risk myelodysplastic syndromes, as well as for patients whose lower-risk myelodysplastic syndromes are refractory to other therapies.[22]

Azacitidine (75 mg/m^2 subcutaneously or intravenously daily for 7 days every month, given until disease progression or toxicity) can delay progression to AML, improve quality of life, and increase median survival from 15 to 24 months.[A6] Cytopenias and gastrointestinal symptoms are the most common adverse effects of this class of drugs.

Decitabine under expert supervision also can delay disease progression. Short courses of this agent may yield particular benefit in patients with lower-risk myelodysplastic syndrome.[A7] An oral formulation in combination with cedazuridine (i.e., a cytidine deaminase inhibitor that inhibits first-pass metabolism of the decitabine) provides responses similar to injectable decitabine.[23]

Although at least 50% of patients who receive a hypomethylating agent experience an improvement in at least one cytopenia, the risks of both neutropenia and thrombocytopenia are increased.[A8] These agents are not curative, and the median survival is less than 6 months when patients are unresponsive. No standard of care is available for patients whose disease worsens after treatment with hypomethylating agents. Options under study include[24] azacitidine with either magrolimab, venetoclax,[A9] or sabatolimab.

Immunomodulatory Agents

Patients with loss of chromosome 5q, either alone or in conjunction with other chromosomal abnormalities, have high response rates to lenalidomide, including a nearly 70% rate of transfusion independence and a greater than 30% rate of cytogenetic normalization persisting for a median of more than 2 years.[25] Lenalidomide (10 mg daily) is now the treatment of choice for lower-risk 5q– patients. In patients with lower-risk myelodysplastic syndromes without a chromosome 5 abnormality, the response rate to lenalidomide is approximately 35%; such responses persist for a median of 8 to 9 months.[26] In higher-risk myelodysplastic syndromes and AML with 5q–chromosomal abnormalities, however, it is less effective. Important adverse effects of lenalidomide include cytopenias, thrombosis, diarrhea, and rash.

Immunosuppressive Therapy

Patients who display a pathophysiology similar to aplastic anemia (e.g., T-lymphocyte-driven autoimmune attack against hematopoietic cells) may respond to anti-T-cell therapies, including antithymocyte globulin and calcineurin inhibitors under expert supervision. Younger patients with a normal karyotype, trisomy 8, paroxysmal nocturnal hemoglobinuria clones, or HLA DR15 status seem to have a higher likelihood of benefiting, but good predictive strategies for selecting patients for immunosuppressive therapy are lacking.

PREVENTION

At present there is no clear way by which myelodysplastic syndromes can be prevented, except avoiding known risk factors such as radiation exposure or alkylating agents. However, emerging clonal hematopoiesis following treatment for cancer or arising de novo can now be recognized at an early stage and may be amenable to intervention.[27]

PROGNOSIS

The natural history of myelodysplastic syndromes is highly variable. Approximately one half of patients will die of complications of the cytopenias, particularly infection due to neutropenia and functional neutrophil defects (i.e., impaired bactericidal activity due to hypogranularity). Among lethal infections in myelodysplastic syndromes, pneumonia and bacteremia are most common. Bleeding is the second most common disease-related cause of death. Anemia may exacerbate cardiovascular or cerebrovascular disease. Approximately 25% of patients will progress to AML, which is

Risk group	Included karyotypes	Median survival, years	25% of patients to AML, years	Proportion of patients in this group
Very good	del(11q), –Y	5.4	N/R	4%
Good	Normal, del(20q), del(5q) alone or with 1 other anomaly, del(12p)	4.8	9.4	72%
Intermediate	+8, del(7q), i(17q), +19, any other single or double abnormality not listed	2.7	2.5	13%
Poor	Abnormal 3q, –7, double abnormality include –7/del(7q), complex with 3 abnormalities	1.5	1.7	4%
Very poor	Complex with >3 abnormalities	0.7	0.7	7%

A

Parameter	Categories and associated scores

C

FIGURE 167-3. The 2012 Revised International Prognostic Scoring System (IPSS-R) for myelodysplastic syndromes. A, Cytogenetic abnormalities. **B,** Table for calculation of IPSS-R risk group. **C,** Outcomes by risk group. AML = acute myeloid leukemia. (Data from Greenberg PL, Tuechler H, Schanz J, et al. Revised international prognostic scoring system for myelodysplastic syndromes. *Blood* 2012;120:2454-2465.)

usually a fatal complication.[28] Finally, because myelodysplastic syndromes are often diagnosed in elderly patients or people with a history of cancer, frailty and geriatric comorbid conditions contribute to death in at least one third of patients. The revised International Prognostic Scoring System (see Fig. 167-3) defines five different subgroups of myelodysplastic syndromes with varying risk for death and AML progression.

Molecular abnormalities (including mutations in *EZH2*, *TP53*, or *RUNX1*) are associated with poorer prognosis, and the Molecular International Prognostic Scoring System considers mutations in up to 17 genes to place patients into six prognostic categories.[29] Additionally, the presence of either a *TP53* or RAS pathway mutation predicts poor outcome after hematopoietic stem cell transplantation.

168 THE ACUTE LEUKEMIAS

ROLAND B. WALTER AND FREDERICK R. APPELBAUM

DEFINITION

Normal hematopoiesis (Chapter 142) requires tightly regulated proliferation and differentiation of pluripotent hematopoietic stem cells that become mature blood cells. Acute leukemia begins as a clonal disease that is the result of a malignant event in an early hematopoietic cell. Over time, subsequent mutational events give rise to full-blown leukemia that may be composed of multiple subclones. Instead of proliferating and differentiating normally, the affected cells give rise to progeny that fail to differentiate normally but continue to proliferate in an uncontrolled fashion. As a result, immature myeloid cells in acute myeloid leukemia (AML) or lymphoid cells in acute lymphoblastic leukemia (ALL)—typically called blasts—rapidly accumulate and progressively replace other cells in the bone marrow, thereby diminishing the production of normal red cells, white cells, and platelets. This loss of normal marrow function, in turn, gives rise to the common clinical complications of acute leukemia: anemia, infection, and bleeding. With time, the leukemic blasts pour out into the blood stream and eventually occupy the lymph nodes, spleen, and other organs. If untreated, acute leukemia is often rapidly fatal; most patients die within several weeks to months after diagnosis. With appropriate therapy, however, the natural history of acute leukemia can be markedly altered, and many patients can be cured.

EPIDEMIOLOGY

Incidence

An estimated 20,000 or so new cases of AML and 6600 or so new cases of ALL occur annually in the United States.[1] This incidence of acute leukemia has remained relatively stable in the United States over the past three decades, but there is substantial variation in incidence among and within world regions.[2]

In the United States, the annual deaths are about 11,500 from AML and about 1400 from ALL. Although acute leukemia accounts for only about 2% of cancer deaths, the impact of leukemia is heightened because of the young age of some patients. For example, ALL has a maximum incidence between ages 2 and 10 years, is the most common cancer in children younger than age 15 years, and accounts for one third of all childhood cancer deaths. The incidence of AML gradually increases with age, with a median age at diagnosis of about 67 years and without an early peak.

Determinants

In most cases, acute leukemia develops for no known reason, but sometimes a possible cause can be identified.

Genetic Predisposition

The concordance rate is virtually 100% in identical twins if one twin develops leukemia during the first year of life. An increasing number of germline mutations (e.g., in *RUNX1, CEBPA, GATA2, DDX41, ETV6, IKZF1, PAX5,* and *SAMD9*) are recognized to cause rare syndromes that can lead to acute leukemia without other manifestations.[3] The incidence of acute leukemia is markedly increased in syndromes involving defective DNA repair, such as Fanconi anemia and Bloom syndrome, and in bone marrow failure syndromes associated with ribosomal abnormalities (Chapter 151), including Diamond-Blackfan anemia, Shwachman-Diamond syndrome, and dyskeratosis congenita. Germline mutations in *TP53* (Li-Fraumeni syndrome) and abnormalities in chromosome number, as in Down and Klinefelter syndromes (Chapters 32 and 214), are also associated with an increased incidence of acute leukemia.

Radiation

Ionizing radiation (Chapter 18) is leukemogenic. The incidences of ALL, AML, and chronic myeloid leukemia (CML) are increased in patients given therapeutic radiation and among survivors of the atomic bomb blasts at Hiroshima and Nagasaki. The magnitude of the risk depends on the dose of radiation, its distribution in time, and the age of the individual. Greater risk results from higher doses of radiation delivered over shorter periods to younger patients. In areas of high natural background radiation (often from radon), chromosomal aberrations are reportedly more frequent, but an increase in acute leukemia has not been consistently found. Although some investigations have raised concern about the possible leukemogenic effects of extremely low-frequency nonionizing electromagnetic fields emitted by electrical installations, findings have been inconsistent across studies; if any such effect exists at all, its magnitude is very small.

Oncogenic Viruses

The search for a viral cause of leukemia has been pursued intensely, but only two clear associations have been found. Human T-cell lymphotropic virus type I (HTLV-I), an enveloped, single-stranded RNA virus, is a causative agent of adult T-cell leukemia (Chapter 360), spread either horizontally by sexual contact or blood products or vertically from mother to fetus. This distinct form of leukemia is found within geographic clusters in southwestern Japan, the Caribbean basin, and Africa. Because HTLV-I seropositivity was found with increasing frequency among heavily transfused patients and intravenous drug users, screening of blood products for antibodies to HTLV-I is now routine practice in blood banks in the United States. Epstein-Barr virus (Chapter 348), the DNA herpes family virus that causes infectious mononucleosis, is associated with the endemic African form of Burkitt lymphoma/leukemia (Chapter 171).

Chemicals and Drugs

Heavy occupational exposure to benzene and benzene-containing compounds, such as kerosene and carbon tetrachloride, may lead to marrow damage, which can take the form of aplastic anemia, myelodysplasia, or AML. A link between leukemia and tobacco use (Chapter 363) has been reported.

With the increasing use of chemotherapy and radiotherapy to treat other malignancies, as much as 10% of AMLs and a smaller percentage of ALLs are likely the consequence of prior cancer therapy. Exposure to alkylating agents such as melphalan and the nitrosoureas is associated with a risk for secondary AML, which often manifests initially as a myelodysplastic syndrome (Chapter 167), frequently with abnormalities of chromosomes 5, 7, and 8 but with no distinct morphologic features. These secondary AMLs typically develop 4 to 6 years after exposure to alkylating agents, and their incidence may be increased with greater intensity and duration of drug exposure. Secondary AML associated with exposure to topoisomerase II inhibitors, including the epipodophyllotoxins (teniposide or etoposide) and doxorubicin, tends to have a shorter latency period (1 to 2 years), lacks a myelodysplastic phase, has a monocytic morphology, and involves abnormalities of the long arm of chromosome 11 (band q23) or chromosome 21 (band q22). Because patients frequently receive combination chemotherapy, it is often difficult to identify a single causative agent. On average, secondary leukemia responds less well to treatment than does de novo disease.

168 THE ACUTE LEUKEMIAS

ROLAND B. WALTER AND FREDERICK R. APPELBAUM

DEFINITION

Normal hematopoiesis (Chapter 142) requires tightly regulated proliferation and differentiation of pluripotent hematopoietic stem cells that become mature blood cells. Acute leukemia begins as a clonal disease that is the result of a malignant event in an early hematopoietic cell. Over time, subsequent mutational events give rise to full-blown leukemia that may be composed of multiple subclones. Instead of proliferating and differentiating normally, the affected cells give rise to progeny that fail to differentiate normally but continue to proliferate in an uncontrolled fashion. As a result, immature myeloid cells in acute myeloid leukemia (AML) or lymphoid cells in acute lymphoblastic leukemia (ALL)—typically called blasts—rapidly accumulate and progressively replace other cells in the bone marrow, thereby diminishing the production of normal red cells, white cells, and platelets. This loss of normal marrow function, in turn, gives rise to the common clinical complications of acute leukemia: anemia, infection, and bleeding. With time, the leukemic blasts pour out into the blood stream and eventually occupy the lymph nodes, spleen, and other organs. If untreated, acute leukemia is often rapidly fatal; most patients die within several weeks to months after diagnosis. With appropriate therapy, however, the natural history of acute leukemia can be markedly altered, and many patients can be cured.

EPIDEMIOLOGY

Incidence

An estimated 20,000 or so new cases of AML and 6600 or so new cases of ALL occur annually in the United States.[1] This incidence of acute leukemia has remained relatively stable in the United States over the past three decades, but there is substantial variation in incidence among and within world regions.[2]

In the United States, the annual deaths are about 11,500 from AML and about 1400 from ALL. Although acute leukemia accounts for only about 2% of cancer deaths, the impact of leukemia is heightened because of the young age of some patients. For example, ALL has a maximum incidence between ages 2 and 10 years, is the most common cancer in children younger than age 15 years, and accounts for one third of all childhood cancer deaths. The incidence of AML gradually increases with age, with a median age at diagnosis of about 67 years and without an early peak.

Determinants

In most cases, acute leukemia develops for no known reason, but sometimes a possible cause can be identified.

Genetic Predisposition

The concordance rate is virtually 100% in identical twins if one twin develops leukemia during the first year of life. An increasing number of germline mutations (e.g., in *RUNX1, CEBPA, GATA2, DDX41, ETV6, IKZF1, PAX5,* and *SAMD9*) are recognized to cause rare syndromes that can lead to acute leukemia without other manifestations.[3] The incidence of acute leukemia is markedly increased in syndromes involving defective DNA repair, such as Fanconi anemia and Bloom syndrome, and in bone marrow failure syndromes associated with ribosomal abnormalities (Chapter 151), including Diamond-Blackfan anemia, Shwachman-Diamond syndrome, and dyskeratosis congenita. Germline mutations in *TP53* (Li-Fraumeni syndrome) and abnormalities in chromosome number, as in Down and Klinefelter syndromes (Chapters 32 and 214), are also associated with an increased incidence of acute leukemia.

Radiation

Ionizing radiation (Chapter 18) is leukemogenic. The incidences of ALL, AML, and chronic myeloid leukemia (CML) are increased in patients given therapeutic radiation and among survivors of the atomic bomb blasts at Hiroshima and Nagasaki. The magnitude of the risk depends on the dose of radiation, its distribution in time, and the age of the individual. Greater risk results from higher doses of radiation delivered over shorter periods to younger patients. In areas of high natural background radiation (often from radon), chromosomal aberrations are reportedly more frequent, but an increase in acute leukemia has not been consistently found. Although some investigations have raised concern about the possible leukemogenic effects of extremely low-frequency nonionizing electromagnetic fields emitted by electrical installations, findings have been inconsistent across studies; if any such effect exists at all, its magnitude is very small.

Oncogenic Viruses

The search for a viral cause of leukemia has been pursued intensely, but only two clear associations have been found. Human T-cell lymphotropic virus type I (HTLV-I), an enveloped, single-stranded RNA virus, is a causative agent of adult T-cell leukemia (Chapter 360), spread either horizontally by sexual contact or blood products or vertically from mother to fetus. This distinct form of leukemia is found within geographic clusters in southwestern Japan, the Caribbean basin, and Africa. Because HTLV-I seropositivity was found with increasing frequency among heavily transfused patients and intravenous drug users, screening of blood products for antibodies to HTLV-I is now routine practice in blood banks in the United States. Epstein-Barr virus (Chapter 348), the DNA herpes family virus that causes infectious mononucleosis, is associated with the endemic African form of Burkitt lymphoma/leukemia (Chapter 171).

Chemicals and Drugs

Heavy occupational exposure to benzene and benzene-containing compounds, such as kerosene and carbon tetrachloride, may lead to marrow damage, which can take the form of aplastic anemia, myelodysplasia, or AML. A link between leukemia and tobacco use (Chapter 363) has been reported.

With the increasing use of chemotherapy and radiotherapy to treat other malignancies, as much as 10% of AMLs and a smaller percentage of ALLs are likely the consequence of prior cancer therapy. Exposure to alkylating agents such as melphalan and the nitrosoureas is associated with a risk for secondary AML, which often manifests initially as a myelodysplastic syndrome (Chapter 167), frequently with abnormalities of chromosomes 5, 7, and 8 but with no distinct morphologic features. These secondary AMLs typically develop 4 to 6 years after exposure to alkylating agents, and their incidence may be increased with greater intensity and duration of drug exposure. Secondary AML associated with exposure to topoisomerase II inhibitors, including the epipodophyllotoxins (teniposide or etoposide) and doxorubicin, tends to have a shorter latency period (1 to 2 years), lacks a myelodysplastic phase, has a monocytic morphology, and involves abnormalities of the long arm of chromosome 11 (band q23) or chromosome 21 (band q22). Because patients frequently receive combination chemotherapy, it is often difficult to identify a single causative agent. On average, secondary leukemia responds less well to treatment than does de novo disease.

ABSTRACT

Acute leukemia begins as a clonal disease that is the result of a malignant event in an early hematopoietic cell. With time, subsequent mutational events give rise to full-blown leukemia that may be composed of multiple subclones. Instead of proliferating and differentiating normally, the affected cells give rise to progeny that fail to differentiate but continue to proliferate in an uncontrolled fashion. As a result, immature myeloid cells in acute myeloid leukemia (AML) or lymphoid cells in acute lymphoblastic leukemia (ALL)—called blasts—rapidly accumulate and progressively replace other cells in the bone marrow, thereby diminishing the production of normal red cells, white cells, and platelets. This loss of normal marrow function, in turn, gives rise to the common clinical complications of acute leukemia: anemia, infection, and bleeding. With time, the leukemic blasts pour out into the blood stream and eventually occupy the lymph nodes, spleen, and other organs. If untreated, acute leukemia is often rapidly fatal; most patients die within several weeks to months after diagnosis. With appropriate therapy, however, the natural history of acute leukemia can be markedly altered, and many patients can be cured.

KEYWORDS

acute myeloid leukemia
acute promyelocytic leukemia
acute lymphoblastic leukemia
Philadelphia chromosome
cytogenetic/molecular abnormality
immunophenotype
hematopoietic cell transplantation

PATHOBIOLOGY

Clonality and Cell of Origin

The acute leukemias are clonal disorders, and all leukemic cells in a given patient are descended from a common progenitor. The clonal nature of acute leukemia suggests that leukemic stem cells are capable of both self-renewal and proliferation. Leukemic stem cells in AML are rare among the leukemic mass, with a frequency of 0.2 to 10 per 10^6, and usually, but not invariably, are located within the primitive $CD34^{++}$ $CD38^{-}$ fraction. Less is known about the ALL stem cell.

Classification

The classification of acute leukemias is based on clinical, morphologic, immunophenotypic, cytogenetic, and molecular features (Table 168-1).

TABLE 168-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF ACUTE LEUKEMIAS (2016)

Acute Myeloid Leukemia (AML) and Related Neoplasms
AML with recurrent genetic abnormalities
AML with t(8;21)(q22;q22.1); *RUNX1-RUNX1T1*
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
APL with *PML-RARA*
AML with t(9;11)(p21.3;q23.3); *MLLT3-KMT2A*
AML with t(6;9)(p23;q34.1); *DEK-NUP214*
AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); *GATA2, MECOM*
AML (megakaryoblastic) with t(1;22)(p13.3;q13.3); *RBM15-MKL1*
Provisional entity: AML with BCR-ABL1
AML with mutated NPM1
AML with biallelic mutations of *CEBPA*
Provisional entity: AML with mutated RUNX1
AML with myelodysplasia-related changes
Therapy-related myeloid neoplasms
AML, NOS
AML with minimal differentiation
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monoblastic/monocytic leukemia
Pure erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Transient abnormal myelopoiesis (TAM)
Myeloid leukemia associated with Down syndrome
Blastic Plasmacytoid Dendritic Cell Neoplasm
Acute Leukemias of Ambiguous Lineage
Acute undifferentiated leukemia
Mixed phenotype acute leukemia (MPAL) with t(9;22)(q34.1;q11.2); *BCR-ABL1*
MPAL with t(v;11q23.3); *KMT2A* rearranged
MPAL, B/myeloid, NOS
MPAL, T/myeloid, NOS
B-Lymphoblastic Leukemia/Lymphoma
B-lymphoblastic leukemia/lymphoma, NOS
B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities
B-lymphoblastic leukemia/lymphoma with t(9;22)(q34.1;q11.2); *BCR-ABL1*
B-lymphoblastic leukemia/lymphoma with t(v;11q23.3); *KMT2A* rearranged
B-lymphoblastic leukemia/lymphoma with t(12;21)(p13.2;q22.1); *ETV6-RUNX1*
B-lymphoblastic leukemia/lymphoma with hyperdiploidy
B-lymphoblastic leukemia/lymphoma with hypodiploidy
B-lymphoblastic leukemia/lymphoma with t(5;14)(q31.1;q32.3); *IL3-IGH*
B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3); *TCF3-PBX1*

Morphology

Leukemic blasts in AML are typically 12 to 20 µm in diameter, with discrete nuclear chromatin, multiple nucleoli, and cytoplasm that usually contains azurophilic granules (Fig. 168-1). Auer rods, which are slender, fusiform cytoplasmic inclusions that stain red with Wright-Giemsa stain, are virtually pathognomonic of AML (Fig. 168-2).

The leukemic cells in ALL tend to be smaller than AML blasts and relatively devoid of granules (see Fig. 168-1). ALL can be divided by French-American-British criteria based on size, nuclear chromatin appearance, nucleoli, and cytoplasm/granules. However, this morphologic classification scheme has been largely replaced by schemes that consider immunologic and cytogenetic characteristics.

Immunophenotyping

Immunophenotyping by multiparameter flow cytometry is used to determine lineage involvement of newly diagnosed acute leukemias and to detect aberrant immunophenotypes, thereby allowing quantification of measurable residual disease after therapy.

Acute Myeloid Leukemia

Most cases of AML express antigens seen on normal immature myeloid cells. The most immature forms of AML express CD34, CD117, and human leukocyte antigen (HLA)-DR, whereas more differentiated forms express CD13 and CD33. CD14, CD15, and CD11b are expressed by AMLs with monocytic features; erythroid leukemias express CD36, CD71, and CD235a (glycophorin A); and megakaryocytic AMLs express CD41 and CD61. In 10 to 20% of patients, otherwise typical AML blasts also express antigens usually restricted to B- or T-cell lineage (e.g., CD2, CD7, CD19, or CD56). Expression of a

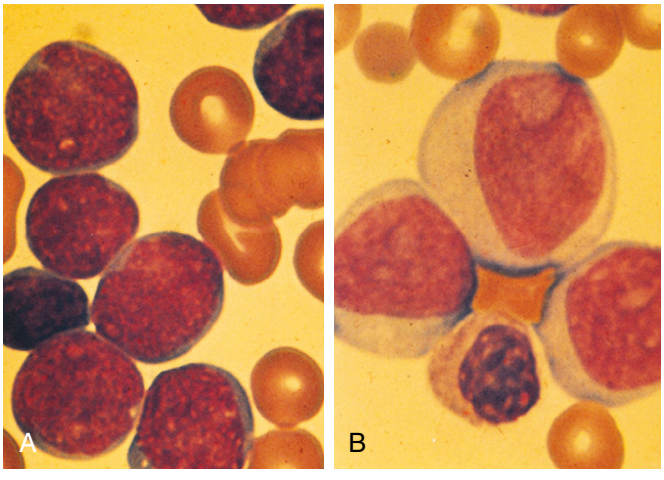

FIGURE 168-1. Acute leukemia. A, Acute lymphoblastic leukemia (ALL). **B**, Acute myeloid leukemia (AML). Lymphoblasts in ALL are smaller, with a higher ratio of nuclear to cytoplasmic material and less distinct nucleoli than in the myeloblasts in AML. The nucleoli in the myeloblasts are clear and "punched out."

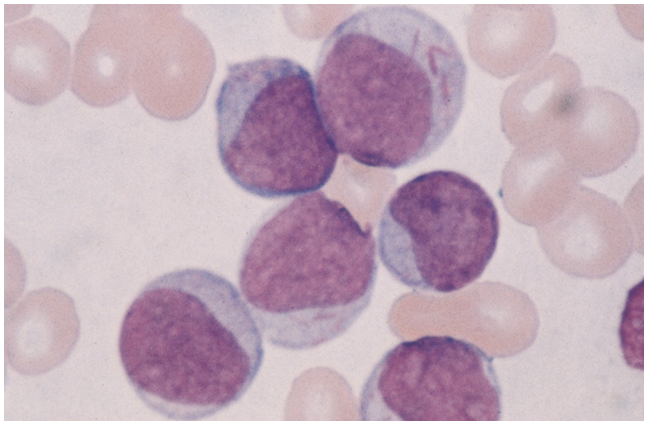

FIGURE 168-2. Acute myeloid leukemia. The myeloblasts in the smear show Auer rods as cytoplasmic inclusions.

single lymphoid antigen by AML cells does not change either the natural history or the therapeutic response of these leukemias.

Acute Lymphoblastic Leukemia

Approximately 75% of cases of ALL express B-lineage antigens and can be subdivided into four categories. The most immature group, previously called pro-B ALL, expresses the early B-cell antigens CD19 and/or CD22 but not CD10 and represents about 10% of cases of ALL. Approximately 50 to 60% of cases of ALL express CD19 and/or CD22 along with the common ALL antigen (CALLA, or CD10), a glycoprotein that is also found occasionally on normal early lymphocytes. CALLA-positive ALL is thought to represent an early pre–B-cell differentiation state. Approximately 10% of cases of ALL have intracytoplasmic immunoglobulin and were previously termed pre–B-cell ALL. The immunophenotypically most mature subset of B-cell ALL is signified by the presence of surface immunoglobulin and accounts for less than 5% of cases of ALL. In general, the best therapeutic outcomes among B-cell ALL types are with CALLA-positive ALL. The 25% of cases of ALL that express T-lineage antigens can be separated immunophenotypically into three groups: (1) those expressing CD7 but not CD1a or CD3 (currently recognized as early T-cell precursor lymphoblastic leukemia), (2) those expressing CD1a but not surface CD3 (previously termed thymic T-ALL), and (3) those expressing surface CD3 (previously termed mature T-ALL). In about 25% of patients with ALL, the leukemic cells may also express a myeloid antigen, but this antigen does not affect responses to current therapies. Although immunophenotyping remains important for ALL, the WHO currently classifies the ALLs largely based on cytogenetic and molecular features (see Table 168-1).

Acute Leukemia of Ambiguous Lineage

Acute leukemias of ambiguous lineage are rare cases with no evidence of lineage differentiation (i.e., acute undifferentiated leukemia) or with blasts that express definitive markers of more than one lineage (i.e., mixed phenotype acute leukemia). Mixed phenotype acute leukemia can contain either distinct blast populations of different lineages (bilineal) or a single population expressing features of both lineages (biphenotypic). In general, the prognosis of patients with acute undifferentiated leukemia or mixed phenotype acute leukemia is poor when treated with standard chemotherapy.

Cytogenetics and Molecular Biology

In most acute leukemias, an abnormality in chromosome number or structure is found. These abnormalities are (oligo)clonal, involving some or all of the malignant cells in a given patient; they are acquired and are not found in the patient's normal cells; and they are referred to as "nonrandom" because specific abnormalities are found in multiple cases and are associated with distinct morphologic or clinical subtypes of the disease. These abnormalities may simply entail the gain or loss of whole chromosomes, but more often they include chromosomal translocations, deletions, or inversions. When patients with acute leukemia and a chromosomal abnormality receive treatment and enter into complete remission, the chromosomal abnormality disappears; when relapse occurs, the abnormality often reappears. In many cases, these abnormalities have provided clues into the pathobiology of acute leukemia.

Acute Myeloid Leukemia

Translocations

The most common cytogenetic abnormalities seen in AML can be categorized according to their underlying biology and prognostic significance.[4,5] The translocation t(8;21) and the inversion inv(16) result in abnormalities of a transcription factor composed of core binding factor-α (CBF-α) and CBF-β. The translocation t(8;21) results in the fusion of CBF-α (*RUNX1*) on chromosome 21 with the *RUNXT1* gene on chromosome 8, whereas the inversion inv(16) results in the fusion of CBF-β (*CBFB*) on the q arm of chromosome 16 with the *MYH11* gene on the p arm. Both of these "core binding factor" AMLs (CBF-AMLs) are characterized by a high complete remission rate and relatively favorable long-term survival for the group as a whole. Comprehensive mutational profiling of CBF-AMLs does, however, reveal clinical prognostic as well as biologic heterogeneity within this pathogenetically unique category of patients.[6] An additional translocation with a favorable prognosis, t(15;17), involves two genes, *PML* and *RAR-α* (a gene encoding the α-retinoic acid receptor), and is invariably associated with acute promyelocytic leukemia. Other genetic alterations may cooperate with *PML-RARα* in the pathogenesis of acute promyelocytic leukemia. Translocations involving the *KMT2A* (previously: *MLL*) gene, located at chromosome band 11q23, are seen in 5 to 7% of AMLs. *KMT2A* is perhaps the most promiscuous oncogene partner in oncology, with more than 130 fusion partners identified. The prognosis of *KMT2A*-associated AML depends on the fusion partner, with t(9;11) predicting an intermediate prognosis but most others considered unfavorable. Trisomy 8 is among the most common nonrandom cytogenetic abnormalities seen in AML; it accounts for 9% of cases and carries an intermediate prognosis. Trisomies of chromosome 21, chromosome 11, and other chromosomes are sometimes seen as well. Deletions of part or all of chromosome 5 or 7 each account for 6 to 8% of cases of AML. These abnormalities are seen with greater frequency in older patients and in patients with AML secondary to myelodysplasia or prior exposure to alkylating agents, and they are associated with an unfavorable prognosis. The presence of multiple (three or more) cytogenetic abnormalities in individual cases of AML defines "complex cytogenetics" and also is associated with an unfavorable prognosis. Particularly unfavorable are cases with a monosomal karyotype (i.e., the presence of two or more distinct monosomies or one monosomy and another structural abnormality), at least partly because of their strong association with mutations in *TP53*.

§These markers should not be used as an adverse prognostic marker if they co-occur with favorable-risk AML subtypes.
AML = acute myeloid leukemia.

Mutations

Assaying for the status of genes that are frequently mutated in AML is slowly becoming standard, with increasing numbers of studies suggesting their utility both for prognosis (Table 168-2) and for the selection of treatment.[7] AML cells appear to carry, on average, about 10 to 15 mutations per cell, far less than found in epithelial cancers. Of these, on average five mutations are in genes recurrently mutated in AML (so-called driver mutations), with the remainder being considered as passenger mutations. Among the recurrently mutated driver mutations, several are of significant therapeutic and prognostic importance and thus are part of the standard evaluation of AML. *CEBPA*, a gene encoding a leucine zipper transcription factor involved in myeloid differentiation, is mutated in 4 to 15% of cases of AML. Biallelic mutations in *CEBPA* are associated with a more favorable prognosis. *NPM1* encodes a nucleolar phosphoprotein with multiple functions. Mutations in *NPM1* are found in approximately 30% of AML cases and are also associated with a more favorable prognosis. As for other genes, co-occurring mutations influence the prognostic significance of *NPM1* mutations. *FLT3* is a receptor tyrosine kinase and is mutated in 30 to 35% of AML patients, about one-fourth of the time as a point mutation and about three-fourths of the time as an internal tandem duplication. Mutations in *FLT3* are associated with a poorer clinical outcome, at least when found at a high allelic ratio. Other driver mutations recurrently mutated in AML include *DNMT3A, IDH1* and *2, NRAS* and *KRAS, RUNX1, TET2, ASXL1*, and *TP53*. Certain mutations (e.g., in *SRSF2, SF3B1, U2AF1*,

ZRSR2, *ASXL1*, *EZH2*, *BCOR*, or *STAG2*) are almost exclusively found in secondary AML and can be used to identify such cases molecularly.

Acute Lymphoblastic Leukemia

Translocations

The most common cytogenetic abnormality seen in adults with ALL is the Philadelphia chromosome, or t(9;22). This translocation results in fusion of the *BCR* gene on chromosome 22 to the *ABL1* tyrosine kinase gene on chromosome 9. The result is the constitutive activation of *ABL1*, but the precise mechanism by which this activity leads to leukemia is unclear. The *BCR-ABL1* fusion is associated with both ALL and CML (Chapter 170), with a difference in the breakpoint of *BCR* distinguishing the two. Specifically, a slightly smaller 190-kD fusion protein is usually found in ALL, whereas a larger 210-kD protein is characteristic of CML. The frequency of t(9;22) in ALL increases with age: it is found in approximately 5% of childhood cases and 25% of adults. Another translocation seen in adult B-cell ALL includes t(4;11), which is seen in 7% of cases, involves the *KMT2A* and *AF4* genes, and has a poor prognosis. t(8;14), which involves *MYC* and the immunoglobulin heavy chain gene, is the translocation associated with a leukemic variant of Burkitt lymphoma (Chapter 171). T-cell ALLs (Chapter 360) are frequently associated with translocations involving chromosomes 7 or 14 at the sites of T-cell receptor enhancer genes on these chromosomes. The other most common cytogenetic abnormalities seen in adult ALL include del(9p), seen in 5 to 9% of cases; del (6q), seen in 5 to 7%; and del(13q), seen in 3 to 5%.

Mutations

As in AML, directed and genome-wide evaluation of cases of ALL have revealed recurrent mutations in addition to those already identified through cytogenetics. Among the most common are mutations in *PAX5* and *IKZF1*, which are seen in 30 and 25% of cases of B-ALL, respectively, and mutations in *NOTCH1*, which are seen in 35% of cases of T-ALL. A poor-risk form of ALL termed Philadelphia chromosome–like ALL accounts for 20 to 25% of adult ALLs.[8] In this type of ALL, leukemia cells lack the classic *BCR-ABL1* translocation and, instead, have kinase-activating mutations in other genes in the same signaling pathway, including *CRLF2*, often in combination with mutations in *JAK2*.

CLINICAL MANIFESTATIONS

The signs and symptoms of acute leukemia, which result from decreased normal marrow function and invasion of normal organs by leukemic blasts, are usually rapid in onset, developing over a few weeks to a few months at most. Anemia, which is present at diagnosis in most patients, causes fatigue, pallor, headache, and, in predisposed patients, angina or heart failure. Thrombocytopenia is usually present, and approximately one third of patients have clinically evident bleeding at diagnosis, usually in the form of petechiae, ecchymoses, bleeding gums, epistaxis, or hemorrhage. Most patients with acute leukemia are significantly granulocytopenic at diagnosis. As a result, approximately one third of patients with AML and slightly fewer patients with ALL have significant or life-threatening infections, mostly of bacterial origin, when initially seen.

In addition to suppressing normal marrow function, leukemic cells can infiltrate other organs. In ALL, which tends to infiltrate normal organs more often than AML, enlargement of lymph nodes, liver, and spleen is common at diagnosis. Patients with T-ALL frequently have mediastinal masses. Bone pain, thought to result from leukemic infiltration of the periosteum or expansion of the medullary cavity, is a common complaint, particularly in children with ALL. Leukemic cells sometimes infiltrate the skin and result in a raised, nonpruritic rash—a condition termed *leukemia cutis*. Leukemic cells may infiltrate the leptomeninges and cause leukemic meningitis, typically manifested by headache and nausea. As the disease progresses, central nervous system (CNS) palsies and seizures may develop. Although less than 5% of patients with ALL have CNS involvement at diagnosis, the CNS is a frequent site of relapse, so CNS prophylaxis is an essential component of the treatment of ALL. Testicular involvement is seen in ALL, and the testicles are a frequent site of relapse.

In AML, collections of leukemic blast cells, often referred to as *chloromas* or *myeloblastomas* or *myeloid sarcomas*, can occur in virtually any soft tissue and appear as rubbery, fast-growing masses. Because the incidence of CNS disease is low in AML, there is no proven benefit of CNS surveillance or prophylaxis.

Certain clinical manifestations are unique to specific subtypes of leukemia. Patients with acute promyelocytic leukemia commonly have subclinical or clinically evident coagulation abnormalities, including disseminated intravascular coagulation (DIC; Chapter 161), caused by tissue thromboplastins released by the leukemic cells. AMLs with monocytic or myelomonocytic differentiation are most likely to have extramedullary involvement. Pure erythroid leukemia often has a long prodromal phase.

DIAGNOSIS

Abnormalities in peripheral blood counts are usually the initial laboratory evidence of acute leukemia, with anemia and thrombocytopenia being almost universal. Up to 25% of patients have severe thrombocytopenia (platelets <20,000/μL). Although most patients are granulocytopenic at diagnosis, the total peripheral white cell count is more variable; approximately 25% of patients have very high white cell counts (>50,000/μL), approximately 50% have white cell counts between 5000 and 50,000/μL, and about 25% have low white cell counts (<5000/μL). In most cases, blasts are present in the peripheral blood, although the percentage of blasts is quite low or absent in some patients.

The diagnosis of acute leukemia is typically established by marrow aspiration (or biopsy if an aspirate cannot be obtained), usually from the posterior iliac crest. Marrow aspirates and biopsy specimens are usually hypercellular and contain 20 to 100% blast cells, which largely replace the normal marrow (see Figs. 168-1 and 168-2). Occasionally, other abnormalities, such as marrow fibrosis (especially with acute megakaryoblastic leukemia) or bone marrow necrosis, are present in addition to the blast cell infiltrate. Marrow samples also should be evaluated for cytogenetic and molecular abnormalities, which are important for classification, prognostication, and guiding therapeutic decision making (see Table 168-2). A diagnostic lumbar puncture is generally recommended in all patients who have ALL but not in patients who have AML in the absence of CNS symptoms.

The prothrombin and partial thromboplastin times are sometimes elevated. In acute promyelocytic leukemia, reduced fibrinogen and evidence of DIC are often seen (Chapter 161). Other laboratory abnormalities frequently present include hyperuricemia, especially in ALL, and increased serum levels of lactate dehydrogenase. In cases of high cell turnover and cell death, evidence of *tumor lysis syndrome* (Chapter 164), including hypocalcemia, hyperkalemia, hyperphosphatemia, hyperuricemia, and renal insufficiency, may be noted at diagnosis. This syndrome, which is more commonly seen shortly after therapy is begun, can be rapidly fatal if untreated.

Differential Diagnosis

The diagnosis of acute leukemia is usually straightforward but can occasionally be difficult. Both leukemia and aplastic anemia (Chapter 151) can manifest with peripheral pancytopenia, but the finding of a hypoplastic marrow without blasts usually distinguishes aplastic anemia. An occasional patient has hypocellular marrow and a clonal cytogenetic abnormality, which establishes the diagnosis of myelodysplasia (Chapter 167) or hypocellular leukemia.

A number of processes other than leukemia can lead to the appearance of immature cells in the peripheral blood. Although other small round cell neoplasms can infiltrate the marrow and mimic leukemia, immunologic markers are effective in differentiating the two. *Leukemoid reactions* to infections such as tuberculosis can result in the outpouring of large numbers of young myeloid cells, but the proportion of blasts in marrow or peripheral blood almost never reaches 20% in a leukemoid reaction (Chapter 153). Infectious mononucleosis (Chapter 348) and other viral illnesses can sometimes mimic ALL, particularly if large numbers of atypical lymphocytes are present in the peripheral blood and the disease is accompanied by immune thrombocytopenia or hemolytic anemia.

TREATMENT AND PROGNOSIS

With the development of effective regimens of combination chemotherapy and advances in hematopoietic cell transplantation, many patients with acute leukemia can be cured. These therapeutic measures are complex and are best carried out at centers with appropriate support services and experience in treating leukemia. Because leukemia is often rapidly progressive, specific antileukemic therapy is typically started in a timely manner, usually within about 3 days of presentation. However, the time from diagnosis to treatment in AML is not related to survival, and it may be preferable to wait for a few extra days for genetic or other laboratory test results to become available in patients whose white blood cell counts are not rapidly increasing so that the best available treatment option can be determined. The goal of initial chemotherapy is to induce a complete remission with restoration of normal marrow function. In general, induction chemotherapy is intensive and is accompanied by significant toxicities. Therefore, patients should be stabilized to the extent possible before specific antileukemic therapy is begun.

Preparing the Patient for Therapy

The diagnosis of leukemia usually comes as a profound psychological shock to the patient and family. Therefore, in addition to stabilizing the patient hematologically and metabolically, it is worthwhile to have at least one formal conference in which the patient and family are advised about the meaning of the diagnosis and the consequences of therapy before treatment is initiated.

Severe bleeding usually results from thrombocytopenia, which can be reversed with platelet transfusions (Chapter 162). Once thrombocytopenic bleeding is stopped, continued prophylactic transfusions of platelets is warranted to maintain the platelet count higher than 10,000/μL. Occasionally, patients also have evidence of DIC (Chapter 161), usually associated with the diagnosis of acute promyelocytic leukemia. If acute promyelocytic leukemia is suspected as the cause, all-*trans*-retinoic acid should be started without waiting for molecular confirmation of the diagnosis (Table 168-3); the drug can be discontinued if the diagnosis is not confirmed. If active bleeding is due to DIC, low doses of heparin (50 U/kg) given intravenously every 6 hours can be of benefit. Platelets and fresh-frozen plasma (or cryoprecipitate) should be transfused to maintain the platelet count higher than 50,000/μL and the fibrinogen level greater than 100 mg/dL until the DIC abates. Whether heparin should be given prophylactically to patients with laboratory evidence of DIC but no active bleeding is an often debated but unsettled question.

In patients with fever and granulocytopenia, blood cultures should be obtained, and empiric broad-spectrum antibiotics should be started while awaiting guidance from the results of the blood cultures and sensitivities (Chapters 153 and 260). If the patient has an adequate granulocyte count, it is preferable to bring an infection under control before starting initial chemotherapy. However, patients often have infection but essentially no granulocytes; in this situation, delaying chemotherapy is unlikely to be beneficial.

Patients with very high blast counts may develop symptoms attributable to the effect of masses of these immature cells on blood flow (leukostasis). The role of leukapheresis and/or hydroxyurea in managing such patients is unclear. Randomized trials are lacking, but data in patients with AML and initial white cell counts greater than 100,000/μL show an early death rate of 20%, with neither leukapheresis nor hydroxyurea improving the outcome. Current guidelines thus suggest proceeding to cytoreductive treatment using planned induction therapy as soon as possible.

Before treatment, management in all patients should be aimed at preventing tumor lysis syndrome (Chapter 164). Patients should be hydrated and given allopurinol 100 to 600 mg orally or intravenously daily before chemotherapy is initiated. Allopurinol prevents the conversion of xanthine and hypoxanthine to uric acid but does not affect already formed uric acid. Patients who present with very high white cell counts may have uremia and anuria secondary to greatly increased serum uric acid levels and intratubular crystallization, even before starting therapy; these patients should be treated with intravenous rasburicase[9] under expert supervision to promote the catabolism of already-formed uric acid to allantoin. Urinary alkalinization is not recommended because it increases the possibility that xanthine and calcium phosphate will precipitate in the kidney.

Treatment of Acute Lymphoblastic Leukemia

After the patient's condition has been stabilized, antileukemic therapy should be started as soon as possible. Treatment of newly diagnosed ALL can be divided into three phases: induction of remission, postremission therapy, and CNS prophylaxis.[10]

Induction of Remission

The initial goal of treatment is to induce complete remission, defined as the reduction of leukemic blasts to undetectable levels and the restoration of normal marrow function. A number of different chemotherapeutic combinations can be used to induce remission; all include vincristine and prednisone, and most add L-asparaginase and daunorubicin, administered over a period of 3 to 4 weeks (Table 168-4). With such regimens, complete remission is achieved in 90% of children and 80 to 90% of adults. For adults age 18 to 59 years with CD20-positive, Philadelphia chromosome–negative ALL, the addition of rituximab (beginning with 375 mg/m^2 on days 1 and 7 and continuing for a total of 16 to 18 infusions) improves the outcome.[A1] Because vincristine, prednisone, and L-asparaginase are relatively nontoxic to normal marrow precursors, the disease often enters complete remission after a relatively brief period of myelosuppression. Failure to achieve complete remission is usually due to either the resistance of leukemic cells to the drugs or to progressive infection. These two complications occur with approximately equal frequency.

Postremission Chemotherapy

If no further therapy is given after induction of complete remission, relapse occurs in almost all cases, usually within several months. Chemotherapy after complete remission can be given in a variety of combinations, dosages, and schedules.

Consolidation chemotherapy refers to short courses of further chemotherapy, given in the hospital at doses similar to those used for initial induction. Consolidation chemotherapy usually involves different drugs than were successful for inducing the initial remission; alternatively, drug combinations can be rotated. Such drugs include high-dose methotrexate, cyclophosphamide, and cytarabine, among others. Most regimens include six to eight courses of intensive consolidation therapy. Maintenance involves the administration of low-dose chemotherapy on a daily or weekly outpatient basis for long periods. The most commonly used maintenance regimen in ALL combines daily 6-mercaptopurine and weekly or biweekly methotrexate. The optimal duration of maintenance chemotherapy is unknown, but it is usually given for 2 to 3 years. The use of more intensive regimens similar to those used in the treatment of pediatric ALL are tolerable in patients up to age 40 years and may improve outcomes compared with regimens initially developed for adults.

Central Nervous System Prophylaxis

Most chemotherapeutic agents that are given intravenously or orally do not penetrate the CNS well, and at least 35% of adults with ALL will develop CNS leukemia if no form of CNS prophylaxis is given. With prophylaxis, relapse in the CNS as an isolated event occurs in less than 10% of patients. Systemic chemotherapy with high-dose methotrexate (e.g., 200 mg/m^2 intravenously over 2 hours, followed by 800 mg/m^2 over 22 hours) and cytarabine (e.g., 3 g/m^2 over 2 hours every 12 hours for four doses) can achieve therapeutic drug levels within the CNS. Alternatives are intrathecal cytarabine, intrathecal methotrexate, intrathecal methotrexate combined with 2400 cGy radiation to the cranium, or 2400 cGy to the craniospinal axis.

Treatment of Burkitt-like ALL

Burkitt-like ALL (also called FAB L3 or mature B-cell ALL) is characterized by the presence of monoclonal surface immunoglobulin, cytogenetics showing t(8;14), and the constitutive expression of the *MYC* oncogene. Burkitt-like ALL, which accounts for 3 to 5% of adult cases of ALL, responds well to regimens that incorporate short, intensive courses of high-dose methotrexate (1.5 g/m^2 over 24 hours with leucovorin), cytarabine (3 g/m^2 over 2 hours every 12 hours for four doses), and cyclophosphamide (200 mg/m^2/day for 5 days); this regimen yields high rates of complete response and cures in about 50% of patients. The addition of rituximab may further improve outcomes.

Treatment of Philadelphia Chromosome–Positive ALL

Approximately 5% of pediatric cases and 25% of adult cases of ALL have cytogenetics showing t(9;22), the Philadelphia chromosome. The addition of a tyrosine kinase inhibitor such as imatinib, dasatinib, or ponatinib to conventional chemotherapeutic regimens can provide complete response rates equivalent to those seen in Philadelphia chromosome–negative ALL. Therapy with dasatinib (e.g., 70 mg twice daily for 84 days) and prednisone (e.g., 60 mg/m^2 per day for 24 days followed by a taper and discontinuing on day 32) alone without chemotherapy appears sufficient to allow the majority of older patients with Philadelphia chromosome–positive ALL to achieve an initial morphologic remission, but remissions typically are not durable.[11] However, subsequent treatment

TABLE 168-3 MANAGEMENT OF NEWLY DIAGNOSED ACUTE PROMYELOCYTIC LEUKEMIA

A. Induction—ATRA 45 mg/m^2 orally in divided doses daily plus arsenic trioxide 0.15 mg/kg daily until morphologic remission
B. Consolidation #1—oral arsenic trioxide 0.15 mg/kg/day 5 days/wk for 4 weeks every 8 weeks for total of 4 cycles, and ATRA 45 mg/m^2/day for 2 weeks every 4 weeks for total of 7 cycles

Or, if contraindications to arsenic:

A. Induction: Intravenous ATRA 45 mg/m^2 in divided doses daily plus idarubicin 12 mg/m^2 on days 2, 4, 6, 8
B. Consolidation: Intravenous ATRA 45 mg/m^2 × 15 days + idarubicin 5 mg/m^2 × 4 days × 1 cycle, then ATRA × 15 days plus mitoxantrone 10 mg/m^2 × 3 days × 1 cycle, then ATRA × 15 days + idarubicin 12 mg/m^2 × 1 day × 1 cycle

ATRA = all-*trans*-retinoic acid.

TABLE 168-4 MANAGEMENT OF NEWLY DIAGNOSED ADULT PHILADELPHIA CHROMOSOME–NEGATIVE ACUTE LYMPHOID LEUKEMIA UNDER EXPERT SUPERVISION

A. Induction (and courses 3, 5, 7)—cyclophosphamide 300 mg/m^2 over 3 hr q12h for 6 doses on days 1, 2, 3; doxorubicin 50 mg/m^2 on day 4; vincristine 2 mg/day on days 4 and 11; and dexamethasone 40 mg/day on days 1-4 and days 11-14
B. Consolidation (courses 2, 4, 6, 8)—MTX 200 mg/m^2 over 2 hr, followed by 800 mg/m^2 over 22 hr on day 1; high-dose cytarabine 3 g/m^2 over 2 hr q12h for 4 doses on days 2 and 3
C. Four intrathecal treatments of MTX 12 mg alternating with cytarabine 100 mg are given during the first four courses of systemic therapy

MTX = methotrexate.

with two cycles of blinatumomab (a bispecific antibody to CD19 on ALL cells and CD3 on T cells) can substantially increase the proportion of patients who achieve a molecular remission and is associated with survival expectations exceeding 90% at 18 months.[12]

Treatment of Relapsed ALL

Most relapses occur within 2 years after diagnosis, and most occur in the marrow. Occasionally, relapse is initially found in an extramedullary site such as the CNS or testes. Extramedullary relapse is usually followed shortly by systemic (marrow) relapse and should be considered part of a systemic recurrence. With the use of chemotherapeutic regimens similar to those used for initial induction, 50 to 70% of patients achieve at least a short-lived second remission. If the CNS or testes is the initial site of the relapse, specific therapy with chemotherapy and/or radiation to that site is also required along with systemic retreatment.

Because the prognosis of relapsed leukemia treated with standard chemotherapy alone is so poor, hematopoietic cell transplantation (Chapter 163) is usually recommended in this setting, especially if a morphologic remission is obtained with salvage therapy. Some alternatives to conventional multiagent salvage chemotherapy are available. For example, nelarabine when used as a single agent can induce complete remission in 30% of patients with recurrent T-ALL. The bispecific T-cell engager (BiTE) blinatumomab, which is composed of the single-chain variant fragments of anti-CD19 and anti-CD3 antibodies, improves disease-free and overall survival in patients with recurrent B-ALL[A2,A3] and in patients with B-ALL in first or second morphologic remission who have residual leukemia cells (i.e., measurable residual disease) quantified at more than 0.1%. Inotuzumab ozogamicin, which is a CD22 antibody conjugated to a highly toxic calicheamicin derivative, also can increase the complete remission rate, the duration of remission, and the progression-free survival in adults with relapsed or refractory B-ALL compared with standard intensive chemotherapy,[A4] but with an increased risk of sinusoidal obstruction syndrome (previously termed veno-occlusive disease; Chapter 129). Very high complete responses also have been reported in trials using chimeric antigen receptor T cells targeting CD19 or CD22[13,14] in B-ALL that is refractory or in second or later relapse. Cytokine release syndrome and neurologic toxicity are the most significant side effects.

Hematopoietic Cell Transplantation

The use of high-dose chemoradiotherapy followed by hematopoietic cell transplantation (Chapter 163) from a suitable donor can cure 20 to 40% of patients with ALL who fail to achieve an initial remission or who have a relapse after an initial complete remission; it can cure 50 to 60% of patients who undergo transplantation during a first remission. Despite considerable debate, several studies have reported improved survival when adults with high-risk or standard-risk ALL receive a hematopoietic stem cell transplant during a first remission rather than being treated with standard chemotherapy.[A5] The major limitations of transplantation are graft-versus-host disease, infections, and recurrent disease. If an HLA-identical sibling is not available, transplantation from a matched or partially matched unrelated donor or transplantation of cord blood from a partially matched unrelated donor can be conducted, with results that approach those seen with matched related donors.

Prognosis of ALL

A number of factors help predict the outcome in ALL, the most important of which are younger age, a lower white cell count at diagnosis, and favorable cytogenetics (Fig. 168-3). With currently available treatment regimens, 5-year survival has reached 90% for pediatric ALL. In adults, outcomes are less favorable, with 5-year survival rates of 65 to 75% in adolescents and young adults up to age 40 years, less than 20% in individuals older than age 60 years, and less than 45% overall.

Treatment of Acute Myeloid Leukemia

Remission Induction in Medically Fit Adults

Unless patients have contraindications to aggressive therapy, initial treatment generally includes a combination of an anthracycline and cytarabine (the latter at a dose of 100 to 200 mg/m^2/day for 7 days; Table 168-5) and leads to complete remission in 60 to 80% of patients.[15] Prospective randomized trials have demonstrated that for patients aged 65 years or less, idarubicin (10 to 12 mg/m^2/day for 3 days) or a higher dose of daunorubicin (60 to 90 mg/m^2/day for 3 days) is superior to the conventional daunorubicin dose of 45 mg/m^2/day for 3 days.[16] For acute myeloid leukemia with a mutation in isocitrate dehydrogenase 1, adding ivosidenib, which is an inhibitor of it, can prolong median overall survival from 8 months to 24 months.[A6] Profound myelosuppression always follows when these agents are used at doses capable of inducing complete remission. Approximately 50% of patients will have more than 5% blasts remaining in their marrow 1 week after completing the first cycle of induction. Many experts still recommend starting a second cycle in such circumstances, although the benefit of this approach has been questioned.

Persistence of blasts after the first cycle of induction appears to be associated with an increased risk of recurrent disease. In approximately 30% of cases, AML blasts will have mutations in *FLT3*. In such patients, the addition of the *FLT3* inhibitor midostaurin as part of induction (e.g., 50 mg twice daily on days 8 to 21), consolidation (e.g., 50 mg twice daily on days 8 to 21), and maintenance (e.g., 50 mg twice daily for 1 year) leads to improved disease-free and overall survival.[A7] The addition of the CD33 antibody-drug conjugate gemtuzumab ozogamicin to induction and, possibly, consolidation may reduce relapse and improve survival, particularly in patients with favorable-risk disease and, to a lesser extent, patients with intermediate-risk CD33-positive AML. Failure to achieve complete remission is usually due either to drug resistance or to fatal complications of myelosuppression. In older adults with therapy-related AML or AML with myelodysplasia-related changes, CPX-351, a liposomal formulation of cytarabine co-encapsulated with daunorubicin, leads to better survival than conventional chemotherapy.[A8] With the increasing availability of molecularly targeted agents and lower intensity regimens, a number of chemotherapeutic options are available for the initial therapy of AML in medically fit adults.[17]

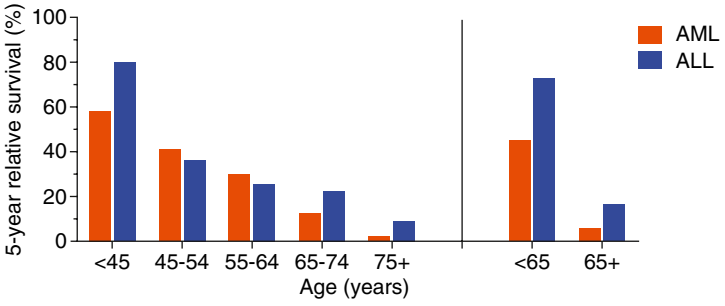

FIGURE 168-3. Shown are the 5-year survival rates (relative to age-matched controls) for adult patients with newly diagnosed acute myeloid leukemia (AML) on the left and acute lymphoblastic leukemia (ALL) on the right according to U.S. Surveillance, Epidemiology and End Results Program (SEER) data.

TABLE 168-5 MANAGEMENT OF NEWLY DIAGNOSED ACUTE MYELOID LEUKEMIA UNDER EXPERT SUPERVISION

A. Induction—daunorubicin 60-90 mg/m^2/day for 3 days (or idarubicin 10-12 mg/m^2/day for 3 days) and cytarabine 100-200 mg/m^2/day for 7 days
   1. At least for favorable-risk disease—add gemtuzumab ozogamicin 3 mg/m^2 (up to 4.5 mg) on days 1, 4, and 7
   2. For *FLT3*-mutated AML—add oral midostaurin 50 mg twice daily on days 8-21
   3. Older adults with therapy-related AML and AML with myelodysplasia-related changes—CPX-351 (100 mg/m^2 cytarabine, 44 mg/m^2 daunorubicin) on days 1, 3, and 5

B. Postremission
   1. Favorable risk—cytarabine 3 g/m^2 over 3 hr q12h on days 1, 2, and 3 every month for 4 months; may add gemtuzumab ozogamicin 3 mg/m^2 (up to 4.5 mg) on day 1 for first 2 cycles
   2. Intermediate risk—as for favorable risk; or, if HLA-matched related or unrelated donor exists, allogeneic hematopoietic cell transplantation
   3. Unfavorable risk—proceed to allogeneic transplantation if possible; if not, treat as for intermediate risk
   4. For *FLT3*-mutated AML—add oral midostaurin 50 mg twice daily on days 8-21
   5. Older adults with therapy-related AML and AML with myelodysplasia-related changes—CPX-351 (65 mg/m^2 cytarabine, 29 mg/m^2 daunorubicin) on days 1 and 3 for 1-2 cycles

AML = acute myeloid leukemia; CPX-351 = liposomal cytarabine-daunorubicin; *FLT3* = FMS-like tyrosine kinase 3; HLA = human leukocyte antigen.

Postremission Therapy

Intensive consolidation chemotherapy with repeated courses of daunorubicin and cytarabine at doses similar to those used for induction, high-dose cytarabine (1 to 3 g/m^2/day for 3 to 6 days), or other agents prolongs the average duration of remission and improves the chances for long-term, disease-free survival. The best results reported to date have generally been achieved with repeated cycles of high-dose cytarabine. Maintenance therapy with CC-486, an oral formulation of azacitidine, significantly improves median overall (from 15 to 25 months) and relapse-free (from 5 to 10 months) survival in older adults who are in remission after intensive induction/postremission therapy and cannot undergo allogeneic hematopoietic cell transplantation.[A9] In AML, recurrent leukemia occurs less often in the CNS (approximately 10% of cases) than in patients with ALL, most commonly in patients with monocytic or myelomonocytic differentiation of AML blasts. There is no evidence that CNS prophylaxis improves survival in AML.

Based on cytogenetics and molecular testing, the favorable outcomes after initial therapy are in patients who have t(8;21) or inv(16), patients who have

normal cytogenetics but biallelic mutated *CEBPA*, and patients who have mutated *NPM1* and either wild-type *FLT3* or low-allelic-ratio *FLT3*-ITD (see Table 168-2). Intermediate-risk patients have normal cytogenetics without mutations in *NPM1*, *CEBPA*, and *FLT3* (or *FLT3*-ITD with a low allelic ratio) or with high-allelic-ratio *FLT3*-ITD in combination with a mutation in *NPM1*. Also at intermediate risk are patients with t(9;11) or those with cytogenetic abnormalities not classified as favorable or unfavorable. Patients with an unfavorable prognosis have high-allelic-ratio inv(3), t(6;9), −5 or del5, or −7 or del7; a high-allelic-ratio *FLT3*-ITD, and wild-type *NPM1*; mutations in *RUNX1*, *ASXL1*, or *TP53*; or complex cytogenetics (three or more independent chromosome abnormalities).

Treatment of Recurrent AML

Patients in complete remission by morphologic criteria (i.e., ≤5% blasts in the bone marrow) may still have some residual leukemic disease not identified by light microscopy. Both multiparameter flow cytometry-based methods, which rely on identification of abnormal immunophenotypes, and molecular-based methods detecting chimeric fusion proteins or somatic mutations can detect and quantify residual disease, which identifies patients with a high risk of subsequent recurrent disease and worse overall survival.

About 50% of patients whose AML recurs after initial chemotherapy can achieve a second remission after retreatment with daunorubicin-cytarabine or high-dose cytarabine. The likelihood of achieving a second remission is predicted by the duration of the first remission: 70% in patients whose first remission persisted beyond 2 years, compared with less than 15% in those whose first remission lasted less than 6 months. Enasidenib and ivosidenib, oral targeted inhibitors of mutant *IDH2* and *IDH1*, respectively, have been approved for the treatment of patients with recurrent *IDH*-mutated AML based on nonrandomized studies. For the treatment of patients with recurrent *FLT3*-mutated AML, the tyrosine kinase inhibitor gilteritinib (120 mg daily) improves median survival by about 3.5 months compared with standard salvage chemotherapy.[A10]

Second remissions tend to be short-lived, however, and few patients in whom relapse occurs after first-line chemotherapy are cured by salvage chemotherapy. Therefore, hematopoietic cell transplantation is generally indicated, especially if a morphologic remission is obtained with salvage therapy.

Hematopoietic Cell Transplantation

For patients with AML in whom an initial remission cannot be achieved or for those who relapse after chemotherapy, hematopoietic cell transplantation (Chapter 163) from an HLA-identical sibling offers the best chance for cure. Allogeneic transplant is most effective when performed in AML patients who are in complete remission both morphologically and by measurable residual disease testing. Patients with measurable residual disease at the time of transplant are at increased risk for post-transplant relapse.[18]

Meta-analyses confirm that allogeneic transplantation from an HLA-matched sibling improves survival compared with chemotherapy in patients who are in a first remission with unfavorable-risk disease. By comparison, the benefits of hematopoietic cell transplantation are less clear in patients with intermediate-risk disease and probably do not extend to patients with favorable-risk AML in remission, especially if the cytogenetics are favorable. The major limitations of allogeneic hematopoietic cell transplantation are lack of a matched sibling donor, graft-versus-host disease, infections related to immunosuppression, and recurrent disease. Because transplant-related toxicities increase with patient age, some centers limit hematopoietic cell transplantation to patients 65 years of age or younger. However, recent studies of reduced-intensity allogeneic transplantation have shown encouraging results in patients with AML in remission at ages up to 75 years. Allogeneic transplantation using HLA-matched unrelated donors results in survival essentially equivalent to that seen using matched siblings, although there is a higher incidence of complications. In experienced centers, survival outcomes with HLA-haploidentical donors have also approached those seen with HLA-matched patients. Similarly, cord blood transplantation results in cure rates similar to those seen with HLA-matched unrelated transplants and may result in reduced relapse rates in patients with measurable residual disease at the time of transplant. Autologous hematopoietic cell transplantation offers an alternative for patients without matched siblings to serve as donors. In randomized trials, autologous transplantation after consolidation chemotherapy has significantly prolonged the duration of disease-free survival for patients with AML in first remission, but it has not altered overall survival compared with chemotherapy alone.

Treatment of AML in Patients Not Candidates for Intensive Therapy

The benefits of intensive chemotherapy are reduced in older, medically less-fit patients. Traditional alternatives to intensive chemotherapy include supportive care alone, low-dose cytarabine, or use of a DNA methyltransferase inhibitor (e.g., azacitidine or decitabine). For example, in patients age 65 years or older with newly diagnosed AML, azacitidine can increase median overall survival from 6.5 months to 10.4 months compared with conventional care regimens (best supportive care or standard induction chemotherapy or low-dose cytarabine), and its safety was consistent with its known safety profile in other trials.[A11] The oral BCL2 inhibitor venetoclax combined with azacitidine can double the complete remission rate from 18% to 37% and increase median survival from 14.7 to 20.5 months compared with azacitidine alone.[A12] As a result, the combination of venetoclax and azacitidine has become a new standard of care for medically less-fit adults with newly diagnosed AML. Venetoclax also can be used with low-dose cytarabine. For the same target patient population, the hedgehog signaling pathway inhibitor glasdegib has been approved for use together with low-dose cytarabine based on data from a randomized trial showing an increase in median survival from 4.9 to 8.8 months.[A13] Uncontrolled studies suggest that a 10-day course of decitabine may be superior to shorter courses, especially in patients with adverse-risk AML, including those with *TP53* mutations.

In older patients with AML who are ineligible for intensive chemotherapy, single-agent gemtuzumab ozogamicin, as compared with best supportive care (including hydroxyurea), modestly improves overall survival without excess serious adverse events.[A14]

Prognosis of AML

Among patients in whom complete remission is achieved, 20 to 40% remain alive in continuous complete remission for more than 5 years, suggesting a probable cure. As with ALL, younger patients (see Fig. 168-3) and those with a low white cell count at diagnosis have a more favorable outcome.

Fifteen percent of patients with refractory disease can be saved by hematopoietic cell transplantation. If the transplant is performed earlier, the outcome is better: 50 to 60% of patients are cured if hematopoietic cell transplantation is performed during the first remission, but only approximately 30% of patients who are treated with hematopoietic cell transplantation at first relapse or during second remission are cured.

Patients who have a preleukemic phase before their disease evolves into acute leukemia and those whose leukemia is secondary to prior exposure to chemotherapy also have a poorer prognosis. Any measurable residual disease following induction and consolidation greatly increases the risk of subsequent relapse.

Treatment and Prognosis of Other Acute Leukemias

Treatment of Acute Promyelocytic Leukemia

The combination of all-*trans*-retinoic acid (45 mg/m^2/day until complete remission is achieved) together with arsenic trioxide without any chemotherapy is superior to all-*trans*-retinoic acid plus an anthracycline for patients with low- to intermediate-risk acute promyelocytic leukemia (i.e., those who present with white blood cell counts <10,000/μL)[A15] and is preferred as first-line treatment.[19] For patients with high-risk disease, therapy with all-*trans*-retinoic acid/retinoic acid should be combined with either gemtuzumab ozogamicin or idarubicin, or all-*trans*-retinoic acid can be added to combination chemotherapy. Patients treated with all-*trans*-retinoic acid usually have their coagulation disorders corrected within several days. A unique toxicity of all-*trans*-retinoic acid in the treatment of acute promyelocytic leukemia is the development of hyperleukocytosis accompanied by respiratory distress and pulmonary infiltrates. This differentiation syndrome responds to temporary discontinuation of all-*trans*-retinoic acid and the addition of corticosteroids. In patients who have recurrent acute promyelocytic leukemia and who were not previously treated with all-*trans*-retinoic acid/arsenic trioxide or who have late relapse after all-*trans*-retinoic acid/arsenic trioxide therapy, arsenic trioxide (0.15 mg/kg/day until complete remission is achieved) ± all-*trans*-retinoic acid with or without an anthracycline or gemtuzumab ozogamicin is effective.

Treatment of Blastic Plasmacytoid Dendritic-Cell Neoplasm

Blastic plasmacytoid dendritic-cell neoplasm is a rare, aggressive malignancy with fewer than 1000 cases annually in the United States. With the newest WHO classification system, it is no longer considered a subtype of AML but, rather, considered a separate disease entity. In adults, it occurs primarily after age 60 years and in a 4:1 male:female ratio. The cause is the malignant proliferation of plasmacytoid dendritic cells that over-express CD123, the interleukin-3 receptor subunit alpha. In some patients, the disease can evolve from myelodysplastic syndrome (Chapter 167).

Bone marrow involvement typically presents as cytopenias. About 80% of patients have skin involvement, usually as brown to purple nodules, often accompanied by purpura. Lymphadenopathy, splenomegaly, and even central nervous system involvement can occur. Fatigue, fever, and night sweats are common. Skin or bone marrow biopsy shows immature plasmacytoid dendritic cells.

Tagraxofusp (SL-401) is an immunoconjugate consisting of IL-3 fused to a truncated diphtheria toxin (7 to 10 mg/kg on days 1 to 5 of each 21-day cycle)[20] that can result in remission in about 70% of cases. Hematopoietic cell transplantation is recommended during first remission. Chemotherapy regimens used for ALL and AML also can provide transient remission. In newly treated patients, about 50% survive for 2 or more years.

Management of Complications

Treatment of acute leukemia, especially AML, is accompanied by a number of complications, the two most serious and frequent being infection and bleeding. During the granulocytopenic period that follows induction and consolidation chemotherapy, the risk for bacterial infection is high. Antibiotic prophylaxis under expert supervision significantly decreases infection-related deaths in afebrile neutropenic patients, with the best results seen with quinolones. Despite

prophylaxis, many patients become febrile while neutropenic, and patients can still develop important infections. The most common bacterial species vary somewhat from medical center to medical center, but *Staphylococcus* (primarily *S. epidermidis*; Chapter 267) and *Enterococcus* species (Chapter 270) are the most frequent gram-positive organisms, whereas *Pseudomonas aeruginosa* (Chapter 282) and enteric organisms such as *Escherichia coli* (Chapter 280) and *Klebsiella* species (Chapter 281) are the most common gram-negative organisms isolated.

Even if no cause for fever is found, bacterial infection should be assumed, and, in general, all patients with fever and neutropenia should receive broad-spectrum antibiotics (Chapters 153 and 260). Monotherapy with an intravenous antipseudomonal agent, such as a carbapenem (e.g., imipenem-cilastatin), a cephalosporin (e.g., cefepime), or an antipseudomonal penicillin (e.g., piperacillin-tazobactam), is recommended as empirical therapy. Vancomycin should not be part of standard coverage in most patients but may be used in those with suspected catheter infections or severe mucositis and in patients with hemodynamic instability or altered mental status. Combination therapy with other gram-negative agents (e.g., aminoglycosides) may be needed. Once begun, antibiotics should be continued until patients recover their granulocyte counts, even if they become afebrile first. If documented bacteremia persists despite appropriate antibiotics, the physician should consider removal of indwelling catheters.

Invasive fungal infections are also common following chemotherapy for acute leukemia and are associated with significant morbidity and mortality. Antifungal prophylaxis is associated with a significant reduction in death from fungal infection in patients with AML receiving induction chemotherapy. Posaconazoles is often considered to be more effective than fluconazole or itraconazole. In addition to being granulocytopenic, patients undergoing induction chemotherapy for leukemia have deficient cellular and humoral immunity, at least temporarily, and therefore are subject to infections common in other immunodeficiency states, including *Pneumocystis jirovecii* infection and a variety of viral infections. *P. jirovecii* infection can be prevented by the prophylactic use of trimethoprim-sulfamethoxazole. In cytomegalovirus (CMV)–seronegative patients, CMV-seronegative or leukocyte-reduced blood products should be used to prevent primary infection (Chapter 347). Herpes simplex (Chapter 345) can often complicate existing mucositis and can be prevented with prophylactic acyclovir. Acyclovir is also useful for the prevention and treatment of herpes zoster (Chapter 346).

Myeloid growth factors (granulocyte or granulocyte-macrophage colony-stimulating factor; Chapter 142), if given shortly after the completion of chemotherapy, shorten the period of severe myelosuppression by, on average, 4 days. In most studies, this accelerated recovery has resulted in fewer days with fever and less use of antibiotics, but it has not improved the complete response rate or altered survival and is currently not recommended after induction chemotherapy.

The platelet count that signals a need for platelet transfusion has been the subject of debate. Platelet transfusions from random donors are recommended at a threshold to 10,000/μL in patients without active bleeding. In contrast, a no-prophylaxis strategy results in more days with bleeding and a shorter time to first bleeding episode and therefore is not recommended.[21] In 30 to 50% of cases, patients eventually become alloimmunized and require the use of HLA-matched platelets (Chapter 162). Transfusion-induced graft-versus-host disease (Chapter 162), manifesting as a rash, low-grade fever, elevated values in liver function tests, and decreasing blood counts, can be prevented by irradiating all blood products before transfusion.

169 CHRONIC LYMPHOCYTIC LEUKEMIA

JENNIFER R. BROWN

DEFINITION

Chronic lymphocytic leukemia is a mature B-cell malignancy in which the neoplastic cells share an immunoglobulin gene rearrangement. The disease involves the blood, bone marrow, lymph nodes, spleen, liver, and often other organs at the time of presentation, but clinical manifestations range from asymptomatic disease that may not require therapy for decades to rapidly progressive disease that soon can be life-threatening. Recent therapeutic advances using targeted therapies can provide prolonged progression-free survival.[1]

EPIDEMIOLOGY

Chronic lymphocytic leukemia (CLL) is the most common leukemia in the Western Hemisphere. In the United States, the annual incidence is over 20,000 cases, the prevalence is nearly 200,000, and approximately 4400 individuals die from the disease each year.[2] The lifetime risk of developing chronic lymphocytic leukemia is approximately 0.6%. From 2006 to 2021, both the incidence and death rates declined.

The median age at diagnosis is 70 years, with approximately one third of patients under age 65 years and 10% under age 55 years. Approximately twice as many men as women are diagnosed with chronic lymphocytic leukemia. The disease is more common among Whites than Blacks or Native Americans and is rare among Asians and Pacific Islanders, even when the latter have moved to the Western Hemisphere.

The risk factors for chronic lymphocytic leukemia are not well defined. Up to 10% of individuals with chronic lymphocytic leukemia have a first-degree relative with the disease. Epidemiologic studies suggest a five- to eight-fold increased risk for chronic lymphocytic leukemia among individuals with one affected first-degree relative, and a 27-fold increase in risk with two affected first-degree relatives. Although families have been reported with Mendelian inheritance over multiple generations, no highly penetrant risk mutations have been identified. However, genome-wide association studies have identified over 40 common alleles of low penetrance, and data suggest that rare variants in the *ATM* gene may also contribute.

Epidemiologic studies suggest a possible increase in risk with exposure to pesticides or living on a farm, but the data are not definitive. Chronic lymphocytic leukemia is recognized as a service-connected illness among Vietnam War veterans who were exposed to Agent Orange. Studies of exposure to radiation at the Chernobyl atomic plant are suggestive, but most studies have not shown a definite association between radiation exposure and the risk of chronic lymphocytic leukemia.

PATHOBIOLOGY

In many patients who have chronic lymphocytic leukemia, lymphoid-primed hematopoietic stem cells give rise to mature B-cells that expand and can

prophylaxis, many patients become febrile while neutropenic, and patients can still develop important infections. The most common bacterial species vary somewhat from medical center to medical center, but *Staphylococcus* (primarily *S. epidermidis*; Chapter 267) and *Enterococcus* species (Chapter 270) are the most frequent gram-positive organisms, whereas *Pseudomonas aeruginosa* (Chapter 282) and enteric organisms such as *Escherichia coli* (Chapter 280) and *Klebsiella* species (Chapter 281) are the most common gram-negative organisms isolated.

Even if no cause for fever is found, bacterial infection should be assumed, and, in general, all patients with fever and neutropenia should receive broad-spectrum antibiotics (Chapters 153 and 260). Monotherapy with an intravenous antipseudomonal agent, such as a carbapenem (e.g., imipenem-cilastatin), a cephalosporin (e.g., cefepime), or an antipseudomonal penicillin (e.g., piperacillin-tazobactam), is recommended as empirical therapy. Vancomycin should not be part of standard coverage in most patients but may be used in those with suspected catheter infections or severe mucositis and in patients with hemodynamic instability or altered mental status. Combination therapy with other gram-negative agents (e.g., aminoglycosides) may be needed. Once begun, antibiotics should be continued until patients recover their granulocyte counts, even if they become afebrile first. If documented bacteremia persists despite appropriate antibiotics, the physician should consider removal of indwelling catheters.

Invasive fungal infections are also common following chemotherapy for acute leukemia and are associated with significant morbidity and mortality. Antifungal prophylaxis is associated with a significant reduction in death from fungal infection in patients with AML receiving induction chemotherapy. Posaconazoles is often considered to be more effective than fluconazole or itraconazole. In addition to being granulocytopenic, patients undergoing induction chemotherapy for leukemia have deficient cellular and humoral immunity, at least temporarily, and therefore are subject to infections common in other immunodeficiency states, including *Pneumocystis jirovecii* infection and a variety of viral infections. *P. jirovecii* infection can be prevented by the prophylactic use of trimethoprim-sulfamethoxazole. In cytomegalovirus (CMV)–seronegative patients, CMV-seronegative or leukocyte-reduced blood products should be used to prevent primary infection (Chapter 347). Herpes simplex (Chapter 345) can often complicate existing mucositis and can be prevented with prophylactic acyclovir. Acyclovir is also useful for the prevention and treatment of herpes zoster (Chapter 346).

Myeloid growth factors (granulocyte or granulocyte-macrophage colony-stimulating factor; Chapter 142), if given shortly after the completion of chemotherapy, shorten the period of severe myelosuppression by, on average, 4 days. In most studies, this accelerated recovery has resulted in fewer days with fever and less use of antibiotics, but it has not improved the complete response rate or altered survival and is currently not recommended after induction chemotherapy.

The platelet count that signals a need for platelet transfusion has been the subject of debate. Platelet transfusions from random donors are recommended at a threshold to 10,000/μL in patients without active bleeding. In contrast, a no-prophylaxis strategy results in more days with bleeding and a shorter time to first bleeding episode and therefore is not recommended.[21] In 30 to 50% of cases, patients eventually become alloimmunized and require the use of HLA-matched platelets (Chapter 162). Transfusion-induced graft-versus-host disease (Chapter 162), manifesting as a rash, low-grade fever, elevated values in liver function tests, and decreasing blood counts, can be prevented by irradiating all blood products before transfusion.

169 CHRONIC LYMPHOCYTIC LEUKEMIA

JENNIFER R. BROWN

DEFINITION

Chronic lymphocytic leukemia is a mature B-cell malignancy in which the neoplastic cells share an immunoglobulin gene rearrangement. The disease involves the blood, bone marrow, lymph nodes, spleen, liver, and often other organs at the time of presentation, but clinical manifestations range from asymptomatic disease that may not require therapy for decades to rapidly progressive disease that soon can be life-threatening. Recent therapeutic advances using targeted therapies can provide prolonged progression-free survival.[1]

EPIDEMIOLOGY

Chronic lymphocytic leukemia (CLL) is the most common leukemia in the Western Hemisphere. In the United States, the annual incidence is over 20,000 cases, the prevalence is nearly 200,000, and approximately 4400 individuals die from the disease each year.[2] The lifetime risk of developing chronic lymphocytic leukemia is approximately 0.6%. From 2006 to 2021, both the incidence and death rates declined.

The median age at diagnosis is 70 years, with approximately one third of patients under age 65 years and 10% under age 55 years. Approximately twice as many men as women are diagnosed with chronic lymphocytic leukemia. The disease is more common among Whites than Blacks or Native Americans and is rare among Asians and Pacific Islanders, even when the latter have moved to the Western Hemisphere.

The risk factors for chronic lymphocytic leukemia are not well defined. Up to 10% of individuals with chronic lymphocytic leukemia have a first-degree relative with the disease. Epidemiologic studies suggest a five- to eight-fold increased risk for chronic lymphocytic leukemia among individuals with one affected first-degree relative, and a 27-fold increase in risk with two affected first-degree relatives. Although families have been reported with Mendelian inheritance over multiple generations, no highly penetrant risk mutations have been identified. However, genome-wide association studies have identified over 40 common alleles of low penetrance, and data suggest that rare variants in the *ATM* gene may also contribute.

Epidemiologic studies suggest a possible increase in risk with exposure to pesticides or living on a farm, but the data are not definitive. Chronic lymphocytic leukemia is recognized as a service-connected illness among Vietnam War veterans who were exposed to Agent Orange. Studies of exposure to radiation at the Chernobyl atomic plant are suggestive, but most studies have not shown a definite association between radiation exposure and the risk of chronic lymphocytic leukemia.

PATHOBIOLOGY

In many patients who have chronic lymphocytic leukemia, lymphoid-primed hematopoietic stem cells give rise to mature B-cells that expand and can

ABSTRACT

Chronic lymphocytic leukemia, which is a low-grade malignancy of mature B cells, has a widely variable clinical course that to some extent can be predicted by key biologic markers. Most newly diagnosed patients are followed without therapy, and a substantial fraction of patients never require any therapy. All patients are at increased risk of infection and secondary malignancies, so they should receive aggressive vaccination and cancer screening as part of their standard care. When patients require therapy, targeted therapies, particularly against Bruton tyrosine kinase and BCL-2, have revolutionized the landscape of the disease by providing effective, well-tolerated oral therapies.

become oligoclonal. The development and progression of one or more of these oligoclones is likely dependent on the acquisition of genetic events that lead to chronic lymphocytic leukemia. About 40% of patients with chronic lymphocytic leukemia carry what is called a stereotyped B-cell receptor, which has hundreds of types. These subgroups of B cell receptors are identical or almost identical to each other, a finding that strongly suggests a role for antigen stimulation in pathogenesis. Some stereotyped subsets of chronic lymphocytic leukemia lymphocytes with identical B cell receptors also carry the same genetic events.[3] Additionally, clones of chronic lymphocytic leukemia cells carry an epigenetic signature, which is similar to the developmental stage of the normal B-cell from which they arose. These genetic events, the B cell receptor structure, and the epigenetic signature all carry significant prognostic importance.

The B-Cell Receptor in Chronic Lymphocytic Leukemia

At the time when chronic lymphocytic leukemia is diagnosed, the population of B cells with a common immunophenotype by flow cytometry also carries and expresses a clonal, rearranged immunoglobulin heavy and light chain gene. Somatic hypermutation can be present, with up to 15% or more variations from germline.[4] Although the degree of somatic hypermutation is a continuum across chronic lymphocytic leukemia, the striking clinical observation is that the disease's behavior and outcome vary tremendously based on a dichotomous cutoff of 2% variation from germline. Patients whose chronic lymphocytic leukemia carries a mutated immunoglobulin heavy chain variable sequence that is more than 2% different from germline, called mutated IGHV, have an indolent course, sometimes not requiring therapy at all. By comparison, patients whose immunoglobulin heavy chain variable sequence is not mutated, defined as 2% or less different than germline and called unmutated IGHV, have higher risk disease. The biologic basis for this prognostic difference is unclear. The gene expression profile of both mutated and unmutated cells resembles a memory B cell and is more similar to each other than to any other normal or malignant B cell. Chronic lymphocytic leukemia with an unmutated immunoglobulin heavy chain variable sequence shows increased activation of the B-cell receptor, which drives survival and proliferation and is likely associated with increased clonal evolution over time. Most of the recurrently mutated cancer genes in chronic lymphocytic leukemia occur predominantly in cells with an unmutated immunoglobulin heavy chain variable sequence. In contrast, although chronic lymphocytic leukemias with mutated immunoglobulin heavy chain variable sequences have B cell receptors, activation is at a lower level, and these chronic lymphocytic leukemias are much less likely to have high risk cytogenetics and somatic mutations. Within a subset, chronic lymphocytic leukemia has similar clinical behavior, and some subsets have been associated with particular somatic mutations, thereby suggesting the possibility of codevelopment or crosstalk between B-cell receptor stimulation/selection and genetic abnormalities.[5]

Chromosomal Abnormalities

Chronic lymphocytic leukemia generally has a stable karyotype with few or no abnormalities, particularly at the time of diagnosis. In contrast to many other hematologic malignancies, balanced translocations are rare in chronic lymphocytic leukemia, which more commonly is associated with unbalanced deletions or amplifications but also usually has a quite stable karyotype. By fluorescence in situ hybridization (FISH) on interphase cells, the most common abnormalities in chronic lymphocytic leukemia are deletion 13q14, deletion 11q22, deletion 17p13, and trisomy 12.[6] Deletion 13q14, which is the most common abnormality in chronic lymphocytic leukemia, is seen in about 55% of patients and is the only abnormality that has been associated with favorable prognosis. In general, however, the prognosis of patients with deletion 13q14, trisomy 12, or normal cytogenetics follows what would be expected based on their *IGHV* mutation status. The highest risk abnormality is deletion 17p13, which deletes one copy of the *TP53* gene and is associated with the poorest prognosis. The second highest risk is deletion 11q22, which deletes one copy of the *ATM* gene. Both of these mutations are strongly associated with unmutated immunoglobulin heavy chain variable sequence, but mutated immunoglobulin heavy chain variable sequence mitigates the prognostic impact of the FISH abnormality. Other findings (e.g., deletion 6q22, trisomy 8, 8q gain, and 8p deletion) are relatively rare, especially at diagnosis, and have generally been associated with more aggressive disease. Cases with more than three to five abnormalities are associated with worse outcomes, but this information is not routinely used for determining prognosis.[7]

Recurrent Somatic Mutations

By next generation sequencing,[8] chronic lymphocytic leukemia has a relatively low mutation rate. Unlike Waldenstrom macroglobulinemia (*MYD88*; Chapter 173) and hairy cell leukemia (*BRAF*), chronic lymphocytic leukemia has no recurrent defining somatic mutation. The most common mutations in chronic lymphocytic leukemia occur in only 15 to 20% of patients and affect the *TP53* gene, *NOTCH1*, *SF3B1*, and *ATM*. Many other cancer genes are mutated in a few percent of cases, thereby making the disease genetically very heterogeneous. Some mutations can be clustered into affected pathways that are thought to be activated in most patients, either genetically or otherwise, and that may act cooperatively to induce disease.

Epigenetics

Methylation patterns in chronic lymphocytic leukemia correspond to the developmental pattern of the antecedent normal B cell and do not vary over the course of the disease.[9] The analysis of methylation patterns identifies three groups (low, intermediate, and high programmed chronic lymphocytic leukemia) that correspond to unmutated immunoglobulin heavy chain variable sequence, a mix of unmutated and mutated immunoglobulin heavy chain variable sequence, and mutated immunoglobulin heavy chain variable sequence.

Methylation can also silence genes that are sometimes deleted in chronic lymphocytic leukemia. For example, the most common recurrent genetic event in chronic lymphocytic leukemia is deletion 13q14, which removes the *miR-15* and *-16* genes that target *BCL-2*. When they are deleted, *BCL-2* is overexpressed. Interestingly, chronic lymphocytic leukemias that do not carry deletions of 13q14 typically have hypermethylation of that region, and the hypermethylation effectively silences *miR-15* and *-16*. This example of alternative mechanisms resulting in the same key pathogenetic event is believed to apply to other pathways in chronic lymphocytic leukemia (e.g., *NOTCH1* can be activated both mutationally or through stimulation by the microenvironment).

Immune Dysfunction

Patients with chronic lymphocytic leukemia display significant defects in immune function, including hypogammaglobulinemia and functional T-cell defects. Hypogammaglobulinemia can be present at diagnosis and progresses as the burden of disease increases. T cells show evidence of chronic stimulation, with exhaustion that also worsens with an increasing burden of disease. The number of T cells is often increased, but the cells are dysfunctional. Regulatory T cells are also increased. These defects do not always translate into infections in individual patients, but collectively patients with chronic lymphocytic leukemia have a substantially increased risk of infection.

CLINICAL MANIFESTATIONS

More than 75% of patients with chronic lymphocytic leukemia are asymptomatic at diagnosis. Diagnosis is most commonly made when a complete blood count obtained at the time of a routine physical examination or evaluation for an unrelated medical issue shows lymphocytosis. Alternatively, some patients may be identified when small lymph nodes (Chapter 154) are detected on a routine medical examination or sometimes on a mammogram.

Patients who present with symptomatic disease generally have larger lymph nodes, show signs or symptoms of splenomegaly (Chapter 154), have fatigue or dyspnea from anemia, or demonstrate petechiae or bruising from thrombocytopenia. Systemic (B) symptoms of fevers, chills, night sweats, or weight loss are very unusual except when chronic lymphocytic leukemia is very advanced.

Disease-Related Complications

Infectious Complications and Vaccination

Patients with chronic lymphocytic leukemia are immunosuppressed even at the time of diagnosis and are at increased risk of bacterial and viral infections, including reactivations of herpes virus and an increased mortality from coronavirus-2019 (COVID-19) infection. Sinus infections (Chapter 394) are particularly problematic.

Autoimmune Complications

Autoimmune complications, which can occur in up to 25% of patients with chronic lymphocytic leukemia, typically manifest as autoimmune hemolytic anemia (Chapter 146) or immune thrombocytopenia (Chapter 158), or very rarely autoimmune neutropenia (Chapter 153). Systemic autoimmune complications can occur but are also rare.

Autoimmune cytopenias can also arise as a complication of therapy, including purine analogues as well as newer targeted therapies, but they more commonly develop in the setting of progressive chronic lymphocytic leukemia. For many patients who develop an autoimmune complication, the problem is recurrent over the course of disease.

Secondary Malignancies

Additional cancers are common among people with chronic lymphocytic leukemia, probably related to immune suppression and perhaps genetic predisposition. Melanoma and non-melanoma skin cancers (Chapter 188) are especially increased, and non-melanoma skin cancers can be more invasive and more dangerous than in individuals without chronic lymphocytic leukemia. Common solid tumors including prostate (Chapter 186), breast (Chapter 183), colon (Chapter 179), and lung cancer (Chapter 177) are also increased.

Richter Transformation

Richter transformation, which is the development of an aggressive lymphoma in the context of underlying chronic lymphocytic leukemia, affects about 5% of patients,[10] especially heavily pretreated patients. The majority of lymphomas are diffuse large B-cell lymphomas (Chapter 171) that are clinically and genetically related to the underlying chronic lymphocytic leukemia. Patients commonly present with symptoms that include a rapidly enlarging lymph node, severe B symptoms, fatigue, and/or an elevated lactate dehydrogenase level. Biopsy is required to establish the diagnosis, and a positron emission tomographic (PET) scan is often helpful to target the area to biopsy. Diffuse large B-cell transformation that is clonally unrelated to the underlying chronic lymphocytic leukemia represents about 10 to 20% of cases and typically occurs in previously untreated patients.

DIAGNOSIS

The diagnosis of chronic lymphocytic leukemia should be suspected when an elevation of circulating lymphocytes leads to an elevated total white blood count, usually without any other associated abnormalities on the complete blood count. The peripheral blood smear typically shows an increase in mature appearing lymphocytes with smudge cells, which are an artifact when the fragile lymphocytes of chronic lymphocytic leukemia break open, thereby leaving the appearance of a smudge (Fig. 169-1 and E-Fig. 169-1). Higher numbers of smudge cells are associated with more indolent disease.

The most useful test for establishing a diagnosis of chronic lymphocytic leukemia is peripheral blood flow cytometry for lymphoid markers, which determine the immunophenotype of the circulating cells and often are definitive in establishing the diagnosis of chronic lymphocytic leukemia (Table 169-1). The classic immunophenotype in chronic lymphocytic leukemia includes expression of B-cell markers CD19 with dim CD20 and dim surface immunoglobulin; CD23; and the T-cell marker CD5.

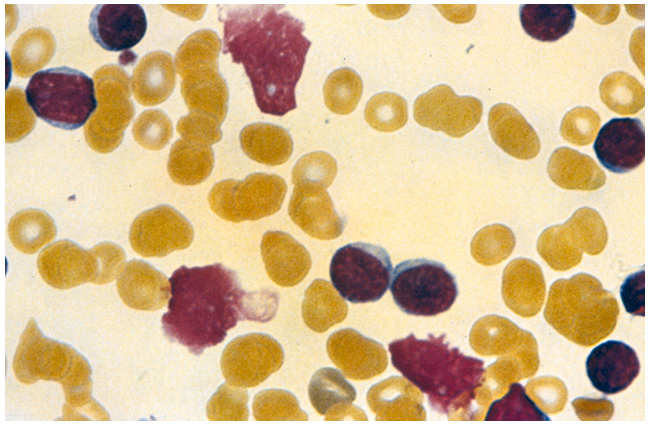

FIGURE 169-1. Chronic lymphocytic leukemia. Peripheral smear shows that the predominant leukocytes are "normal," mature-appearing lymphocytes, with occasional "smudge" cells. (Courtesy Andrew Schafer, MD.)

Differential Diagnosis

Infections such as Epstein-Barr virus (Chapter 348) and cytomegalovirus (Chapter 347) can present with marked lymphocytosis (Chapter 153). However, these and other reactive lymphocytoses are often more pleomorphic on the peripheral blood smear as compared with the lymphocytes of chronic lymphocytic leukemia. Furthermore, flow cytometry will be definitive in the occasional confusing case.

Small Lymphocytic Lymphoma

Small lymphocytic lymphoma (Chapter 171) also has the same immunophenotype as chronic lymphocytic leukemia and historically has been distinguished from chronic lymphocytic leukemia only because its initial presentation is with lymphadenopathy, with less than 5000/μL B lymphocytes in the blood. Currently, chronic lymphocytic leukemia and small lymphocytic lymphoma are considered the same disease and the choice of therapy is the same, so this distinction is of limited importance.

Monoclonal B-Cell Lymphocytosis

Essentially all patients diagnosed with chronic lymphocytic leukemia have had a preexisting subclinical phase called monoclonal B-cell lymphocytosis.[11] Monoclonal B-cell lymphocytosis is diagnosed when the circulating number of B lymphocytes is less than 5000/μL in the absence of cytopenias, lymphadenopathy, or splenomegaly. Many patients with this very low level of lymphocytosis have been told that they have chronic lymphocytic leukemia, when in fact they only meet criteria for monoclonal B-cell lymphocytosis. These monoclonal lymphocytic cells may be detected up to 77 months prior to the diagnosis of chronic lymphocytic leukemia. Although all patients with chronic lymphocytic leukemia have a pre-existing monoclonal B-cell lymphocytosis phase, most patients with monoclonal B-cell lymphocytosis will not progress to develop chronic lymphocytic leukemia.

Monoclonal B-cell lymphocytosis as detected by highly sensitive flow cytometry is very rare before age 40 years, but its prevalence increases to approximately 5% at age 60 years and as high as 45% at age 85 years. The incidence of monoclonal B-cell lymphocytosis is about twice as high among individuals in families with chronic lymphocytic leukemia compared with the general population of similar age.

Monoclonal B-cell lymphocytosis is divided into low-count (<500/μL monoclonal B-cells) disease, which is not detectable on a complete blood count and has a distinct pattern of B-cell receptor gene usage, and high-count (>500/μL but <5000μL monoclonal B-cell lymphocytosis) disease, which is usually identified on a complete blood count and has a B-cell receptor pattern gene usage that is similar to low-risk chronic lymphocytic leukemia.[12] High-count monoclonal B-cell lymphocytosis carries a 1 to 2% per year risk of progressing to chronic lymphocytic leukemia that requires therapy and about a 30% risk of becoming chronic lymphocytic leukemia over 7 years of follow-up, with the primary predictor of progression being a higher lymphocyte count at baseline. However, only 75% of high-count monoclonal B-cell lymphocytosis have a chronic lymphocytic leukemia phenotype, and careful clinical evaluation is warranted to exclude alternative diagnoses including non-Hodgkin lymphomas (Chapter 171).

Other Lymphoid Diseases

Other lymphoid diseases that can present with similar lymphocytosis on a blood smear include marginal zone lymphoma, lymphoplasmacytic lymphoma, mantle cell lymphoma, follicular lymphoma (Chapter 171), and hairy cell

leukemia. More aggressive B-cell lymphomas and mature T-cell leukemia/lymphoma (Chapter 171) can also circulate in the blood but are not difficult to distinguish morphologically from chronic lymphocytic leukemia.

Marginal zone lymphoma (Chapter 171) that is predominantly circulating or splenic is usually the most challenging disease to differentiate from chronic lymphocytic leukemia. Marginal zone lymphoma and lymphoplasmacytic lymphoma are typically negative for both CD5 and CD10, but they can sometimes express CD5 dimly. In these situations, clinical features and cytogenetic or mutational profiles (see Table 169-1) can help establish the most likely diagnosis, but some patients also exhibit features that span more than one diagnosis.

Among the low-grade B-cell diseases, CD5 positivity with CD10 negativity is a key differentiator that excludes follicular lymphoma, which is typically CD10 positive, and hairy cell leukemia, which is typically CD5 negative as well as positive for CD103, CD11c, and CD25. The other B-cell disease that expresses CD5 is mantle cell lymphoma, which can usually be distinguished from chronic lymphocytic leukemia because of the absence of CD23 and positivity for expression of cyclin D1 by immunohistochemistry and/or presence of t(11;14) juxtaposing the cyclin D1 gene with the immunoglobulin heavy chain gene.

Staging and Prognostic Factors

Chronic lymphocytic leukemia can be staged clinically using the Rai system (Table 169-2), which is based on the assessment of lymphadenopathy and organomegaly on physical examination as well as on the complete blood count. However, most patients are diagnosed with early-stage disease, and additional testing (Table 169-3) is useful to help inform prognosis. Among these risk factors, *TP53* aberration and immunoglobulin heavy chain variable mutational status are the most important.

TREATMENT

General Considerations

Very few patients with chronic lymphocytic leukemia require therapy at the time of diagnosis. Asymptomatic patients without cytopenias can be observed, sometimes for decades, and up to 30% of patients never require disease specific therapy. Nevertheless, referral to a specialist is important to confirm the diagnosis, to educate patients about complications, and to provide appropriate counseling and reassurance so patients can adjust to the diagnosis and to the possibility of not receiving therapy for a seemingly ominous condition.

Guidelines suggest the initiation of therapy when cytopenias reach a critical level (e.g., hemoglobin concentration <10 g/dL, platelet count <80-100,000/μL) or when patients develop bulky progressive or symptomatic lymphadenopathy (>10 cm), splenomegaly, significant disease-related symptoms, or difficult-to-control autoimmune hemolytic anemia or immune thrombocytopenic purpura.[13,14] The absolute lymphocyte count itself is not an indication for therapy, although its increase over time often correlates with slowly progressive anemia, thrombocytopenia, and increasing infections that can herald the need for therapy.

Before the initiation of therapy, a full-body computed tomographic scan should be considered in patients who have lymphadenopathy, and a bone marrow biopsy should be considered in patients who have cytopenias. Prognostic markers, such as del(17p), *TP53* mutation, and karyotype analysis, can evolve over time and should be reassessed before each new line of therapy (Table 169-3). Immunoglobulin heavy chain variable sequence mutation status remains stable and does not need to be repeated. If possible, any recommended vaccinations should be completed. Screening for prior hepatitis B infection is important because most therapies reactivate hepatitis B. Chronic active hepatitis B carriers should be on suppressive therapy (Chapter 135) with no detectable viral load before the initiation of any therapy.

Choosing among Medications

Classes of therapy in current use in chronic lymphocytic leukemia include Bruton tyrosine kinase inhibitors, venetoclax (a BCL-2 inhibitor), phosphatidylinositol 3-kinase inhibitors, chemotherapy, immunotherapy, chemoimmunotherapy, and cellular therapy (Table 169-4). Choices are generally determined by the patient's age and comorbid conditions, as well as their disease specific prognostic factors, particularly *TP53* alterations and immunoglobulin heavy chain variable mutation status (Fig. 169-2). Targeted therapies appear to be consistently superior to traditional chemotherapy for both initial treatment and treatment for relapsed or refractory disease (Table 169-5). Once therapy is required, most patients should receive targeted treatment with continuous Bruton tyrosine kinase inhibitor therapy with or without obinutuzumab, or time-limited therapy with venetoclax plus obinutuzumab. Young, fit patients who have favorable mutated immunoglobulin heavy chain gene (IgHV) mutation status and low-risk cytogenetics have the potential of cure with fludarabine/cyclophosphamide/rituximab chemoimmunotherapy.

Most patients are not diagnosed until after age 70 years and are even older by the time that treatment is initiated. Cardiac conditions and the possible need for anticoagulation should be considered prior to beginning treatment with Bruton tyrosine kinase inhibitors, whereas renal dysfunction is an important consideration before venetoclax therapy.[15]

Bruton Tyrosine Kinase Inhibitors

Chronic lymphocytic leukemia cells are dependent on signaling through the B-cell receptor for their growth and survival, and this signaling depends on Bruton tyrosine kinase. When Bruton tyrosine kinase is lost in the germline,

TABLE 169-4 THERAPIES USED IN CHRONIC LYMPHOCYTIC LEUKEMIA

THERAPY	MECHANISM OF ACTION
TARGETED THERAPIES	
Ibrutinib	Irreversible inhibition of BTK
Acalabrutinib	Second-generation irreversible inhibition of BTK
Zanubrutinib	Second-generation irreversible inhibition of BTK
Venetoclax	Inhibition of BCL-2 function
Idelalisib	Reversible inhibition of PI3Kδ
Duvelisib	Reversible inhibition of PI3Kδ,γ
BIOLOGIC THERAPIES	
Obinutuzumab	CD20-directed antibody with enhanced ADCC and direct killing
Rituximab	CD20-directed antibody with ADCC, CDC, and direct killing
Corticosteroids	Microenvironment effect and activation of the steroid receptor
CHEMOTHERAPY	
Chlorambucil	Alkylator/DNA damage
Cyclophosphamide	Alkylator/DNA damage
Bendamustine	DNA damage
Fludarabine	Purine analogue; inhibition of DNA and RNA synthesis and splicing

ADCC = antibody-dependent, cellular-mediated cytotoxicity; BTK = Bruton tyrosine kinase; CDC = complement-dependent cytotoxicity; PI3K = phosphoinositide 3-kinase.

patients lack mature B cells and have agammaglobulinemia as a result. The inhibitor of Bruton tyrosine kinase, ibrutinib (starting dose 420 mg orally daily), binds to Bruton tyrosine kinase covalently, thereby leading to its permanent inactivation.[16] Overall response rates are over 90%, most high-risk patients respond with at least somewhat durable responses, especially when the drug is continued as first-line therapy, and progression-free survival is improved compared with chemoimmunotherapy.[A1–A4]

Continuous therapy with ibrutinib is not possible in many patients because of significant side effects[17] related to the fact that it is not specific for Bruton tyrosine kinase but also potently inhibits 19 other kinases. Second-generation covalent Bruton tyrosine kinase inhibitors, which are more specific and better tolerated, include acalabrutinib (starting at 100 mg orally twice daily), which is FDA approved for the treatment of chronic lymphocytic leukemia at any stage of the disease based on randomized trials demonstrating over a 90% response rate[A5] and improved progression-free survival compared primarily to chemoimmunotherapy.[A6,A7] Zanubrutinib, which has a unique pharmacokinetic profile that maintains circulating drug levels throughout the dosing interval in addition to acting as a covalent inhibitor, is FDA approved for related B-cell malignancies and chronic lymphocytic leukemia. Both acalabrutinib and zanubrutinib[A8] are as efficacious and are substantially better tolerated than ibrutinib in relapsed chronic lymphocytic leukemia, with acalabrutinib showing significant reductions in the cumulative incidence of hypertension, arthralgia, bleeding, and diarrhea.[A9] Both acalabrutinib and zanubrutinib are tolerated by patients who have discontinued ibrutinib because of intolerance. Zanubrutinib also can improve progression-free survival compared with ibrutinib in relapsed CLL, with significantly fewer adverse events.[A10] In the United States, patients with chronic lymphocytic leukemia, particularly patients who are older or have comorbid conditions that put them at particular risk for complications of ibrutinib, should receive a second-generation Bruton tyrosine kinase inhibitor rather than ibrutinib.

With Bruton tyrosine kinase inhibitors, chronic lymphocytic leukemia cells are redistributed from lymph nodes, spleen, or bone marrow into peripheral blood, often resulting in an increase in the white count (called redistribution lymphocytosis) over the first few weeks of therapy, followed by stabilization and slow decline thereafter. Some patients will eventually achieve a normal white blood cell count, whereas other patients will have persistent stable elevation for years. Lymph nodes shrink rapidly and markedly, thereby allowing evaluation of response despite the increase in white count. Cytopenias also improve, sometimes rapidly but sometimes slowly over up to 6 months. Bruton tyrosine kinase inhibitors do not readily induce apoptosis in chronic lymphocytic leukemia cells, so they do not clear all disease. As a consequence, most patients have durable partial responses but the Bruton tyrosine kinase inhibitor must be continued indefinitely to sustain response.

Complications of Bruton tyrosine kinase inhibitors include a high incidence of cardiac side effects, particularly atrial fibrillation (in 10 to 20% of patients after 2 years on therapy) and hypertension (incidence ranging from 23 to 75% depending on the series), but ventricular arrhythmias, sudden death, conduction block, heart failure, and stroke can also occur. All of these side effects appear to be substantially less likely with acalabrutinib[A11] and zanubrutinib. All Bruton tyrosine kinase inhibitors can cause significant bruising and bleeding, so they must be discontinued for 7 days before and after any major surgical procedure and for 3 days before and after any minor procedure. The covalent Bruton tyrosine kinase inhibitors can be combined safely with single drug anti-platelet therapy (i.e., aspirin), but care must be taken if they are to be combined with anticoagulation, and dual anti-platelet therapy is usually best avoided. If anticoagulation is needed, warfarin is contraindicated and direct oral anticoagulants are preferred. Other side effects frequently leading to the discontinuation of ibrutinib include arthralgias, fatigue, infections, and cytopenias.

Venetoclax

Venetoclax inhibits BCL-2, which is universally overexpressed in chronic lymphocytic leukemia, and blocks apoptosis through direct binding and inhibition of pro-apoptotic proteins. Venetoclax, which is specific for BCL-2, is efficacious in patients with relapsed refractory chronic lymphocytic leukemia, in whom it can provide complete remissions. For example, 2 years of treatment with venetoclax plus rituximab is significantly better than bendamustine plus rituximab in terms of response rates, progression-free survival, and overall survival in heavily pretreated patients.[A12,A13] Even in previously untreated patients, 1 year of treatment with venetoclax plus obinutuzumab is superior to chlorambucil-obinutuzumab with

TABLE 169-5 REPORTED SUCCESS RATES FOR TREATMENT OF CHRONIC LYMPHOCYTIC LEUKEMIA

TREATMENT	PROGRESSION-FREE SURVIVAL	OVERALL SURVIVAL
PREVIOUSLY UNTREATED PATIENTS		
Fludarabine, cyclophosphamide, and rituximab	50% at 57 months	50% at 12.7 years
Bendamustine and rituximab	50% at 42 months	92% at 3 years
Chlorambucil and obinutuzumab	50% at 29 months	Not available
Acalabrutinib	78% at 48 months	88% at 48 months
Acalabrutinib and obinutuzumab	87% at 48 months	93% at 48 months
Venetoclax and obinutuzumab	74% at 48 months	85% at 48 months
Ibrutinib	70% at 5 years	83% at 5 years
RELAPSED OR REFRACTORY DISEASE		
Ibrutinib	50% at 52 months	55% at 7 years
Acalabrutinib	62% at 45 months	>90% at 16 months
Venetoclax	50% at 25 months	84% at 24 months
Venetoclax and rituximab	50% at 54 months	82% at 5 years

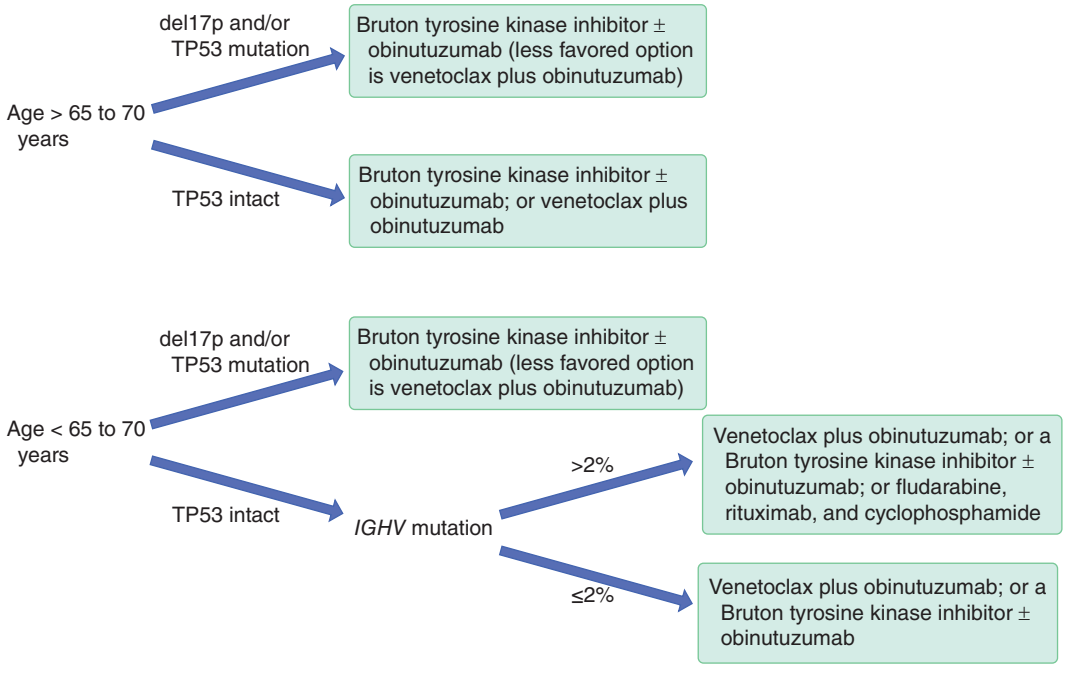

FIGURE 169-2. **Guide to the initial treatment of chronic lymphocytic leukemia.** *IGHV* = immunoglobulin heavy chain variable region.

marked improvement in progression-free survival and deep remissions without detectable residual disease in over 50% of patients,[A14] but all patients eventually relapse. Current investigations are focusing on combining venetoclax with Bruton tyrosine kinase inhibitors, also in time-limited regimens.[18,19] For example, 1 year of ibrutinib plus venetoclax is effective in older patients or patients with comorbid conditions.[A15] The goal of these time-limited regimens is to achieve deep remissions that allow patients substantial time without therapy, with the potential to resume therapy if and when relapse occurs. Venetoclax is also active in chronic lymphocytic leukemia patients whose disease has progressed on a prior Bruton tyrosine kinase inhibitor therapy, albeit with less durability than when it is used as frontline therapy or in patients at the time of first relapse.

The primary side effect of venetoclax is rapid induction of tumor cell death, thereby leading to potentially life-threatening tumor lysis syndrome (Chapter 164). As a result, approved administration starts at a low dose (20 mg orally daily) and is then increased weekly over 5 weeks to the full planned dose of 400 mg orally daily, with laboratory monitoring under expert supervision to avoid the tumor lysis syndrome. Venetoclax is very well tolerated, but other side effects include myelosuppression, nausea, vomiting, and diarrhea.

Immunotherapy

The most successful form of immunotherapy in chronic lymphocytic leukemia is monoclonal antibody therapy. CD20 is a B-cell specific antigen, so off-target effects are limited.

Obinutuzumab is a humanized, glycoengineered anti-CD20 antibody with antibody-dependent cellular cytotoxicity against tumor cells. Obinutuzumab provides better clinical responses and progression-free survival compared with rituximab, so it generally is the antibody of choice in chronic lymphocytic leukemia. For example, obinutuzumab is more potent than rituximab, however, and leads to a significant benefit in terms of progression-free survival when added to acalabrutinib.

The addition of rituximab to ibrutinib has no benefit for progression-free survival.[A16] Rituximab is now mostly used to treat autoimmune cytopenias or in combination with venetoclax.

Chemoimmunotherapy

The combination of CD20 antibodies with chemotherapy leads to synergistic benefit, with nearly universal overall response as well as a marked increase in rates of complete remission (30 to 70%) and durable remissions. For example, the addition of rituximab to chemotherapy with fludarabine plus cyclophosphamide increases overall response, complete response, progression-free survival, and overall survival. Patients with a mutated immunoglobulin heavy chain gene can achieve very prolonged progression-free survival with this regimen, with more than 50% still in remission at 12 years follow-up, thereby suggesting possible cure. Patients with unmutated immunoglobulin heavy chain genes generally experience relapse, but a subset with trisomy 12 can also have durable benefit. Fludarabine/cyclophosphamide/rituximab is preferred over bendamustine rituximab in terms of progression-free survival.[A17] The side effects of fludarabine/cyclophosphamide/rituximab include myelosuppression and a risk of secondary myeloid malignancy, both of which are worse with increasing age, thereby leading to the recommendation that fludarabine/cyclophosphamide/rituximab be considered only in young, fit patients with normal renal function.

Bendamustine plus rituximab can be used palliatively in older patients. Additionally, for older, less-fit patients, the combination of obinutuzumab plus chlorambucil is well tolerated and superior to chlorambucil alone. However, targeted therapy with a Bruton tyrosine kinase inhibitor or with venetoclax plus obinutuzumab provides better progression-free survival if it can be tolerated.[A18]

Phosphatidylinositol 3-kinase (PI3K) δ inhibitors

Like the Bruton tyrosine kinase inhibitors, the PI3Kδ inhibitors also inhibit B-cell receptor signaling downstream of the B-cell receptor. Options include idelalisib (150 mg orally twice daily) and duvelisib (25 mg orally twice daily). Because of substantial toxicity when used as front-line therapy (e.g., neutropenia, bacterial and opportunistic infections, severe colitis, pneumonitis, and elevated aminotransferase levels), these agents are limited to patients who have relapsed chronic lymphocytic leukemia after at least two prior regimens, both Bruton tyrosine kinase inhibitors and venetoclax, or who have comorbid conditions that preclude the use of these drugs.[20]

Refractory Disease

Patients with disease that has progressed despite continuous Bruton tyrosine kinase inhibitor therapy can respond to venetoclax, but durability is limited. Patients whose disease has progressed after both a Bruton tyrosine kinase inhibitor and venetoclax have limited treatment options, because neither PI3K inhibitors nor chemoimmunotherapy have established activity in this particular setting.

For refractory disease, allogeneic stem cell transplantation (Chapter 163) holds the promise of potential cure, but treatment-related mortality is 10 to 20%, and many patients have long-term chronic graft-versus-host disease. Furthermore, the efficacy of transplant is strongly dependent on the patient being in a deep remission, which is often not achievable.

Autologous chimeric antigen receptor (CAR) T-cell therapy is an emerging option for refractory disease. This treatment involves the engineering of the patient's own T cells with a chimeric T cell antigen receptor against a target on the B-cell malignancy, most commonly CD19. CAR T therapy has revolutionized the treatment of relapsed diffuse large B-cell lymphoma (Chapter 171), but results to date in chronic lymphocytic leukemia have been more modest. Possible explanations include the difficulty of collecting autologous T cells due to prior therapy, impaired function of collected T cells due to immune dysfunction, and impaired expansion of the CAR T cells either in vitro or in vivo after infusion, again due to the immune milieu related to chronic lymphocytic leukemia. The coadministration with Bruton tyrosine kinase inhibitors may mitigate some of these problems, but it is not known whether CAR T therapy has the same potential for cure that is offered by allogeneic stem cell transplantation.

Disease-Related Complications

Infections

Patients should be evaluated promptly for any fever, with a low threshold for antibiotic treatment with antimicrobial agents. Vaccination is strongly recommended, including yearly influenza vaccine, COVID-19 vaccine,[21] pneumococcal 20-valent conjugate vaccine followed at least 2 months later by pneumovax (which is then repeated every 5 years), and herpes zoster vaccination (Chapter 15). Studies generally demonstrate measurable but reduced response to these vaccines in patients with chronic lymphocytic leukemia, owing to their immune dysfunction. Patients with chronic lymphocytic leukemia should not receive live-attenuated vaccines because of the risk of disseminated disease arising from the vaccine. If patients have low IgG levels and develop recurrent bacterial infections, intravenous immune globulin replacement under expert supervision can substantially mitigate these infections. For sinus infections, regular sinus irrigation can help substantially.

Autoimmune Complications

When patients with chronic lymphocytic leukemia develop an autoimmune cytopenia, it can be treated with corticosteroids, the anti-CD20 antibody rituximab, or cyclosporine under expert supervision. When these complications develop in the setting of progressive disease, definitive therapy is required for the chronic lymphocytic leukemia.

Malignancy

Patients with chronic lymphocytic leukemia are advised to minimize exposure to ultraviolet light, use highly effective sunscreen, have regular dermatology examinations, and complete all other age-appropriate cancer screening. The treatment of any malignancies is generally the same as in other patients if it can be tolerated.

Richter Transformation

Diffuse large B-cell lymphoma (Chapter 171) can be cured with standard combination chemotherapy for lymphoma (Chapter 171) in previously untreated patients, but the median survival, even with aggressive therapy, is poor when the lymphoma occurs in previously heavily treated patients.

Hodgkin lymphoma (Chapter 172) is much less common. Hodgkin disease (Chapter 172) responds to standard combination chemotherapy for Hodgkin lymphoma and has a natural history like that of de novo disease.

PROGNOSIS

Deletion of 17p containing the *TP53* gene is associated with shorter time to needing treatment, poorer progression-free survival, and shorter overall survival. However, the era of targeted therapies has substantially improved outcome for these patients, with high response rates to targeted therapy albeit still generally shorter progression-free survivals.[22] Deletion 11q, which affects the *ATM* gene, is associated with a pattern of bulky lymphadenopathy, shorter time to treatment, and a shorter durability of remission; however, targeted therapies appear to mitigate this impact. *NOTCH1* mutation is another higher risk mutation that has been associated with an increased risk of Richter transformation. β_2 microglobulin is an extracellular protein component of the human leukocyte antigen (HLA) class 1 complex that associates with prognosis in many B-cell malignancies, most notably multiple myeloma but also chronic lymphocytic leukemia.

Immunoglobulin heavy chain variable sequence status similarly predicts shorter survival for early-stage patients, with older data from before the era of targeted therapy showing that unmutated *VH* genes predict an approximately 8-year survival compared with over 24 years for patients who have mutated *VH* genes. However, continuous Bruton tyrosine kinase inhibitor therapy can control disease for prolonged periods even in patients with unmutated immunoglobulin heavy chain variable sequence.

OTHER CHRONIC LYMPHOCYTIC LEUKEMIAS

HAIRY CELL LEUKEMIA

Hairy cell leukemia, which is an indolent mature B-cell leukemia, is about five times more common in men than women and usually presents in patients aged 50 to 70 years. Most patients present with pancytopenia and marked splenomegaly without lymphadenopathy.[23] Typical mature hairy cells (which have thin cytoplasmic projections, a kidney-shaped nucleus, and one or two distinct nucleoli; Fig. 169-3) infiltrate the bone marrow, spleen, and liver. Because of a paucity of monocytes, tubercular and fungal infections are common. Diagnosis is based on finding the typical cells in the bone marrow. This leukemia is treated under expert supervision with purine analogues, which often lead to prolonged progression-free survival.[24] Vemurafenib, which is an oral BRAF inhibitor, combined with an anti-CD20 antibody also has substantial activity.[25]

PROLYMPHOCYTIC LEUKEMIA

In B-cell prolymphocytic leukemia, more than >55% of the circulating lymphocytes are prolymphocytes. These prolymphocytes are much larger than normal lymphocytes and have a typically round nucleus, with one clear punched-out nucleolus. Approximately 60% of patients have a translocation targeting *MYC*, and about 40% have a 17p deletion affecting *TP53*. B-cell prolymphocytic leukemia is quite rare as a presenting diagnosis, but some patients with chronic lymphocytic leukemia, typically patients with a 17p deletion, have a subset of cells that are similar to prolymphocytic leukemia cells. As the disease progresses, the distinction can pose a diagnostic dilemma, but the immunophenotype of B-cell prolymphocytic leukemia typically will differ from chronic lymphocytic leukemia by expressing surface immunoglobulin and CD20 brightly, not expressing CD23, and sometimes not expressing CD5. The targeted B-cell receptor pathway inhibitors that are effective in chronic lymphocytic leukemia also are effective for prolymphocytic leukemia, so the need to distinguish between these two diseases may be less important.

LARGE GRANULAR LYMPHOCYTIC LEUKEMIA

Large granular lymphocyte leukemia is discussed in Chapter 151.

170 CHRONIC MYELOID LEUKEMIA

JERALD RADICH

DEFINITION

Chronic myeloid leukemia (CML) is a hematopoietic stem cell disease caused by the reciprocal translocation of gene sequences from the breakpoint cluster region (*BCR*) gene on chromosome 22 with the tyrosine kinase sequences of the Abelson (*ABL*) gene on chromosome 9. On a cytogenetic level, this results in an elongated chromosome 9 and a shortened chromosome 22, the latter known as the Philadelphia (Ph) chromosome. The unique chimeric fusion protein, *BCR-ABL*, is a constitutively active tyrosine kinase that drives the pathogenesis of the disease. Thus, *BCR-ABL* represents the target for tyrosine kinase inhibitor therapy as well as a direct measure of disease burden. As described further below, there can be cases of "Ph-" CML, where the Ph chromosome is not detected, but other methods (fluorescence in situ hybridization [FISH], polymerase chain reaction [PCR]) can detect the chimeric *BCR-ABL*. There is no *BCR-ABL*-negative CML, and such diseases as "atypical" CML and chronic neutrophilic leukemia have distinct genetic features that identify them as unique disease entities (discussed briefly later).

CML is categorized in different phases (chronic, accelerated, and blast phases) based on bone marrow and peripheral blood blast counts, additional cytogenetic abnormalities besides the Ph chromosome, and clinical features such as fever. There are several classification schemes, including those proposed by the European Leukemia Network and the World Health Organization (WHO). The main difference between the European Leukemia Network and WHO classifications is the definition of accelerated phase and blast phase: the European Leukemia Network defines accelerated phase as peripheral or bone marrow blast counts of at least 15% to less than 30%, and blast phase as blasts counts greater than or equal to 30%, whereas in the WHO classification, these values are at least 10 to 20% and greater or equal to 20%, respectively. Of note, the WHO criteria are rarely used in clinical practice or clinical trials. More than 75% of CML cases in the developed world are diagnosed in the

OTHER CHRONIC LYMPHOCYTIC LEUKEMIAS

HAIRY CELL LEUKEMIA

Hairy cell leukemia, which is an indolent mature B-cell leukemia, is about five times more common in men than women and usually presents in patients aged 50 to 70 years. Most patients present with pancytopenia and marked splenomegaly without lymphadenopathy.[23] Typical mature hairy cells (which have thin cytoplasmic projections, a kidney-shaped nucleus, and one or two distinct nucleoli; Fig. 169-3) infiltrate the bone marrow, spleen, and liver. Because of a paucity of monocytes, tubercular and fungal infections are common. Diagnosis is based on finding the typical cells in the bone marrow. This leukemia is treated under expert supervision with purine analogues, which often lead to prolonged progression-free survival.[24] Vemurafenib, which is an oral BRAF inhibitor, combined with an anti-CD20 antibody also has substantial activity.[25]

PROLYMPHOCYTIC LEUKEMIA

In B-cell prolymphocytic leukemia, more than >55% of the circulating lymphocytes are prolymphocytes. These prolymphocytes are much larger than normal lymphocytes and have a typically round nucleus, with one clear punched-out nucleolus. Approximately 60% of patients have a translocation targeting *MYC*, and about 40% have a 17p deletion affecting *TP53*. B-cell prolymphocytic leukemia is quite rare as a presenting diagnosis, but some patients with chronic lymphocytic leukemia, typically patients with a 17p deletion, have a subset of cells that are similar to prolymphocytic leukemia cells. As the disease progresses, the distinction can pose a diagnostic dilemma, but the immunophenotype of B-cell prolymphocytic leukemia typically will differ from chronic lymphocytic leukemia by expressing surface immunoglobulin and CD20 brightly, not expressing CD23, and sometimes not expressing CD5. The targeted B-cell receptor pathway inhibitors that are effective in chronic lymphocytic leukemia also are effective for prolymphocytic leukemia, so the need to distinguish between these two diseases may be less important.

LARGE GRANULAR LYMPHOCYTIC LEUKEMIA

Large granular lymphocyte leukemia is discussed in Chapter 151.

170 CHRONIC MYELOID LEUKEMIA

JERALD RADICH

DEFINITION

Chronic myeloid leukemia (CML) is a hematopoietic stem cell disease caused by the reciprocal translocation of gene sequences from the breakpoint cluster region (*BCR*) gene on chromosome 22 with the tyrosine kinase sequences of the Abelson (*ABL*) gene on chromosome 9. On a cytogenetic level, this results in an elongated chromosome 9 and a shortened chromosome 22, the latter known as the Philadelphia (Ph) chromosome. The unique chimeric fusion protein, *BCR-ABL*, is a constitutively active tyrosine kinase that drives the pathogenesis of the disease. Thus, *BCR-ABL* represents the target for tyrosine kinase inhibitor therapy as well as a direct measure of disease burden. As described further below, there can be cases of "Ph-" CML, where the Ph chromosome is not detected, but other methods (fluorescence in situ hybridization [FISH], polymerase chain reaction [PCR]) can detect the chimeric *BCR-ABL*. There is no *BCR-ABL*-negative CML, and such diseases as "atypical" CML and chronic neutrophilic leukemia have distinct genetic features that identify them as unique disease entities (discussed briefly later).

CML is categorized in different phases (chronic, accelerated, and blast phases) based on bone marrow and peripheral blood blast counts, additional cytogenetic abnormalities besides the Ph chromosome, and clinical features such as fever. There are several classification schemes, including those proposed by the European Leukemia Network and the World Health Organization (WHO). The main difference between the European Leukemia Network and WHO classifications is the definition of accelerated phase and blast phase: the European Leukemia Network defines accelerated phase as peripheral or bone marrow blast counts of at least 15% to less than 30%, and blast phase as blasts counts greater than or equal to 30%, whereas in the WHO classification, these values are at least 10 to 20% and greater or equal to 20%, respectively. Of note, the WHO criteria are rarely used in clinical practice or clinical trials. More than 75% of CML cases in the developed world are diagnosed in the

ABSTRACT

Chronic myeloid leukemia (CML) is a myeloproliferative disorder marked by the increased proliferation of a granulocytic cell line that retains the ability to differentiate. As many as 95% of patients with CML have the Philadelphia (Ph) chromosome caused by the reciprocal translocation of the long arms of chromosome 22 at the breakpoint cluster region (*BCR*) gene and chromosome 9 at the Abelson leukemia virus (*ABL*) gene (t[9;22]). As a result of this translocation, a *BCR-ABL* fusion gene is created that generates a chimeric protein with constitutively active tyrosine kinase activity. Tyrosine kinase inhibitor therapy has revolutionized the treatment of CML, giving patients with chronic phase disease a near-normal age-adjusted lifespan. For patients with chronic phase CML, the "first-generation" tyrosine kinase inhibitor imatinib gives a complete cytogenetic remission in roughly 60 to 70% of cases, a major molecular response (a three-log reduction of peripheral blood *BCR-ABL* mRNA) in 50 to 60% of cases, with overall survival rates of more than 90%. The "second-generation" tyrosine kinase inhibitors (e.g., dasatinib, nilotinib, and bosutinib) are more potent than imatinib and thus give higher short-term response rates and less progression to advanced phases of disease, although without a clear advantage in overall survival rates. Because of the success of tyrosine kinase inhibitors, CML will become a more prevalent oncologic diagnosis in the future, despite its relatively low incidence. CML is thus becoming an increasing part of most oncology practices, and an understanding of the pathobiology, monitoring, and treatment is important to optimize the management of CML patients.

chronic phase, whereas the proportion of cases of advanced (accelerated and blast) phase disease is higher in the developing world. Untreated chronic phase CML will eventually progress to advanced phase within a mean period of approximately 3 to 5 years, and when disease reaches blast crisis, the natural history is survival of less than 1 year.

EPIDEMIOLOGY

The incidence of CML is fairly uniform throughout the world, affecting about 1 to 1.5 per 100,000 of the adult population each year.[1] In the Western industrialized world, CML represents approximately 15% of all adult and less than 5% of all childhood leukemias, with a median age of onset of about 65 years. The median age appears to be earlier in the developing world. As a result of the spectacular success of tyrosine kinase inhibitor therapy (see later), the prevalence of CML is increasing steadily because the average duration of the disease has lengthened appreciably.

There are no described "CML families." The greatest risk factor for CML is radiation exposure, particularly in Japanese atomic bomb blast survivors. Although *ABL* sequences are found in the Abelson murine leukemia retrovirus, no infectious agent for human CML has been described.

PATHOBIOLOGY

The Ph chromosome is an acquired cytogenetic abnormality present in all leukemic cells of the myeloid lineage and in some B cells and T cells in CML patients. It is formed as a result of a reciprocal translocation of genetic material of chromosomes 9 and 22 expressed as t(9;22)(q34;q11) (Fig. 170-1). The Ph chromosome is found in more than 90% of CML patients, whereas approximately 5% of cases have translocations that involve chromosomes 9, 22, and others as well. The remaining 5% of patients with clinical and hematologic features consistent with CML have undetectable Ph chromosome, but *BCR-ABL* can be detected by FISH (which detects the DNA fusion) or reverse transcription–polymerase chain reaction (RT-PCR), which detects the chimeric mRNA.

Three possible breakpoints in the *BCR* gene exist, including breaks in the *major* breakpoint cluster region (M-BCR) in the intron between exons e13 and e14 or in the intron between exons e14 and e15.[2] These breakpoints account for more than 95% of CML cases. The breakpoint in the *ABL* gene is varied and can occur broadly upstream of exon a2. Thus, the two possible common *BCR* breakpoints, merging with the *ABL* breakpoint, can yield two slightly different chimeric *BCR-ABL* genes, which yields a longer e13a2 or slightly smaller e14a2 transcript. Both transcripts are translated into a 210-kD BCR-ABL tyrosine kinase ($p210^{BCR-ABL}$) that has greatly enhanced tyrosine kinase activity compared with the normal ABL protein. Rarely in CML, the breakpoint *BCR* occurs 5′ to the common breakpoint between exons e1 and e2 in an area designated the *minor* breakpoint cluster region (m-bcr). This produces the e1a2 mRNA, yielding a smaller *BCR-ABL* fusion gene ($p190^{BCR-ABL}$). Curiously, although this genetic alteration is uncommon in CML, it accounts for roughly half of the cases of Ph chromosome–positive acute lymphoblastic leukemia (ALL).

Very rarely, a breakpoint in the so-called *micro* breakpoint cluster region (μ-bcr) results in e19a2 chimeric mRNA and a larger 230-kD BCR-ABL protein ($p230^{BCR-ABL}$). This molecular lesion appears to be associated with the rare Ph chromosome–positive chronic neutrophilic leukemia.

The normal ABL protein is a nonreceptor tyrosine kinase with important roles in signal transduction and the regulation of cell growth. Normal ABL protein migrates between the cytoplasm and nucleus. The chimeric BCR-ABL protein, however, associates with the cytoplasmic membrane and is constitutively active with increased kinase activity, causing activation of numerous signal transduction pathways, including MYC, RAS, STAT, JUN, and phosphatidylinositol-3 kinase. Unlike many multihit models of carcinogenesis, the single *BCR-ABL* lesion thus appears to influence cell cycling, differentiation, and apoptosis, causing DNA genetic instability and attenuation of the DNA damage response. In murine models, *BCR-ABL* can cause myeloproliferative diseases similar to human CML, although chronic phase has been difficult to simulate until recent sophisticated genetically engineered murine models coupled inducible *BCR-ABL* with the genetic scrambling of the Sleeping Beauty transposon. In vitro studies suggest that *BCR-ABL* expression allows cells to become cytokine independent, protects cells from apoptotic responses to DNA damage, and increases adhesion of hematopoietic cells to extracellular matrix proteins.

The progression to advanced phase disease will eventually occur in all cases not treated with a tyrosine kinase inhibitor or allogeneic transplantation, and advanced phase disease is not curable without transplant (even in the age of tyrosine kinase inhibitors). Progression is associated with a further block in differentiation, with death coming from the eventual absence of normal platelets (bleeding) or white blood cells (infection). Blast counts increase and new cytogenetic abnormalities accumulate. The most common cytogenetic changes in progression are an additional Ph chromosome, trisomy 8, isochrome i(17q), and trisomy 19. Gene expression profiling suggests that the bulk of the

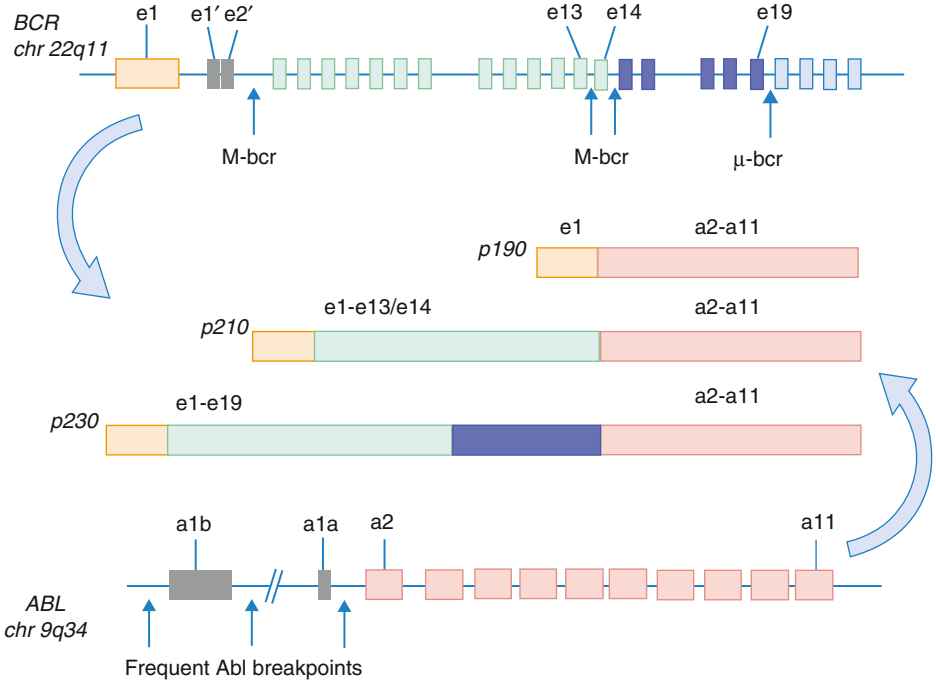

FIGURE 170-1. ***BCR* and *ABL* gene breakpoints.** The *BCR* gene (from chromosome 22) contains three primary breakpoint regions (denoted the "major breakpoint cluster" [M-bcr]; "minor breakpoint cluster" [*m-bcr*]; and "micro breakpoint cluster" [*μ-bcr*]). Gene rearrangement at the *M-bcr* site results in either of two p210 fusion proteins, composed of *BCR* exons 1-13 or exons 1-14 (*orange* and *green*) fused to *ABL* exons 2-11 (*pink*). Gene rearrangement at *m-bcr* site results in the p190 fusion protein, composed of *BCR* exon 1 (e1) (*orange*) fused to *ABL* exons 2-11 (a2-a11) (*pink*). Gene rearrangement at the *μ-bcr* site results in the p230 fusion protein, composed of *BCR* exons 1-19 (*orange*, *green*, and *purple*) fused to *ABL* exons 2-11 (*pink*). The *BCR* e1′ and e2′ are included in the fusion gene, but splicing events result in loss of RNA from the *BCR-ABL* transcript. Fusion transcripts may additionally include *ABL* exons 1a or 1a/1b with exons 2-11, depending on the *ABL* breakpoint region. Not to scale.

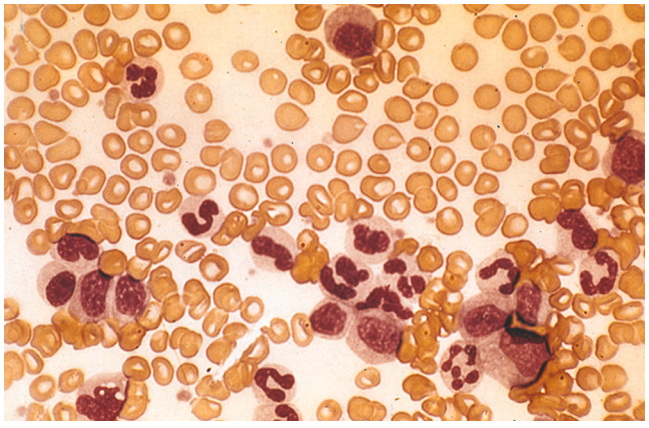

FIGURE 170-2. Chronic myeloid leukemia, chronic phase. Peripheral smear shows leukocytosis, with representation by the entire spectrum of leukocyte differentiation, ranging from myeloblasts to mature neutrophils. (Courtesy Andrew Schafer, MD.)

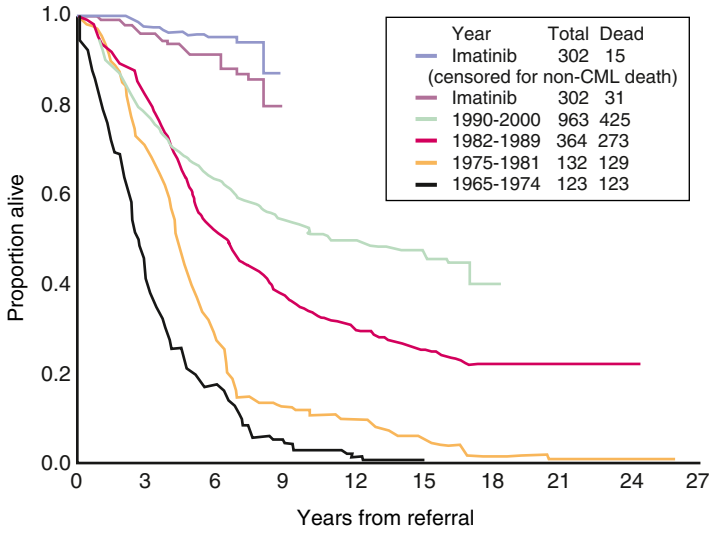

FIGURE 170-3. Survival of patients with Ph chromosome–positive chronic myeloid leukemia (CML) in chronic phase CML. In single-institutional studies, industry-sponsored trials, and national reports where tyrosine kinase inhibitor therapy has full penetration, the estimated 8- to 10-year survival rates are high. The survival rates are lower where tyrosine kinase inhibitor treatment penetration is not optimal. (From Bjorkholm M, Ohm L, Eloranta S, et al. Success story of targeted therapy in chronic myeloid leukemia: a population-based study of patients diagnosed in Sweden from 1973-2008. *J Clin Oncol*. 2011;29:2514-2520, and Chen Y, Wang H, Kantarjian H, et al. Trends in chronic myeloid leukemia incidence and survival in the United States from 1975-2009. *Leuk Lymphoma*. 2013;54:1411-1417.)

genetic changes triggering progression occur from the transition of chronic to accelerated phase, with relatively minor genetic changes occurring from accelerated to blast phase. In keeping with the stem cell origin nature of CML, in about 25% of blast phase cases, the predominant blast expansion is in the lymphoid, not myeloid, lineage.

CLINICAL MANIFESTATIONS

Most CML patients (>90%) present in chronic phase, often diagnosed incidentally during routine examination and blood cell counts. Symptoms, when present, usually include fatigue and abdominal discomfort from splenomegaly. More extreme constitutional symptoms of weight loss, bone pain, fever, and night sweats are more commonly associated with advancing disease. This has practical clinical relevance because although the tyrosine kinase inhibitors used to treat CML (discussed later) are generally well tolerated, compliance early in the treatment course can be challenging because the medications can make patients feel worse than they felt before they were diagnosed.

DIAGNOSIS

Patients generally present with leukocytosis, often accompanied by thrombocytosis and anemia (Fig. 170-2). Basophilia and eosinophilia are common. Without any other obvious explanation for a high white blood cell (WBC) count, the diagnosis of CML can be entertained.[3]

In CML, the diagnostic and monitoring target is the chimeric *BCR-ABL* gene, whether this is at the chromosome level (metaphase cytogenetics), at the DNA level (FISH), or by chimeric mRNA transcript (RT-PCR).

Diagnostic Work-Up

The diagnostic work-up for the suspected CML patient is fairly straightforward, and the goal is to establish both the diagnosis and the phase of disease. A bone marrow aspirate should be evaluated for, at minimum, morphology (to determine blast count) and cytogenetics (to look for the Ph chromosome and other cytogenetic abnormalities that would classify the patient as advanced phase). FISH can be used if the cytogenetic test fails and can be done on peripheral blood if need be. The RT-PCR assay of bone marrow or peripheral blood can be useful to define a "baseline" for later disease monitoring during therapy but is not required. Using peripheral blood RT-PCR testing for *BCR-ABL* can establish diagnosis, but initial diagnostic bone marrow is needed for staging.

TREATMENT

Tyrosine kinase inhibitors are the cornerstone of treatment for CML (Fig. 170-3).[4,5]

Frontline Tyrosine Kinase Inhibitors for CML

There are four FDA-approved tyrosine kinase inhibitors for newly diagnosed chronic phase CML, the "first-generation" tyrosine kinase inhibitor imatinib and three "second-generation" agents, dasatinib, nilotinib, and bosutinib (Table 170-1).[6–8] All work by competitively binding to the adenosine triphosphate (ATP)-binding pocket of BCR-ABL, thus blocking phosphate passage to other downstream signaling effector proteins. In addition, each tyrosine kinase inhibitor has a unique pattern of "off-target" kinase inhibition, which likely explains how the different toxicities of the agents can provide a 67% complete cytogenetic response compared with 7% in the control arm. After more than a decade of follow-up, the cumulative rate of complete cytogenetic response with imatinib is 80 to 85%, with an estimated freedom from progression to progressive disease and overall survival of 92% and 83%, respectively.[A1] Moreover, roughly half all patients with a complete cytogenetic response obtain a major molecular response.

However, the long-term follow-up studies showed that more than 40% of patients discontinue imatinib therapy. These failures of imatinib are roughly divided into thirds: primary resistance to tyrosine kinase inhibitors, intolerance, and resistance/progression after an initial response. Second-generation TKIs (nilotinib, dasatinib, and bosutinib; Table 170-2)[A2–A4] produce superior short-term responses, as measured by rate of complete cytogenetic response and major molecular response by 12 months of therapy. In addition, the second-generation tyrosine kinase inhibitors produce a higher proportion of "deep" molecular responses (which may influence the potential for tyrosine kinase inhibitor discontinuation, discussed later). Transformation to advanced phase disease is less frequent. However, long-term survival has not been significantly different between imatinib and the second-generation tyrosine kinase inhibitors.

Several trials have also compared standard (400 mg/day) to high-dose (600 to 800 mg/day) imatinib. These studies consistently show that high-dose imatinib can yield similar short- and long-term outcomes as the second-generation tyrosine kinase inhibitors. However, these higher doses are less well tolerated and are discouraged as initial therapy in newly diagnosed chronic phase cases.

Toxicities of Tyrosine Kinase Inhibitors

The common side effect of tyrosine kinase inhibitors is myelosuppression, which is less problematic in imatinib than the second-generation tyrosine kinase inhibitors (with grade 3 or 4 cytopenias occurring in roughly 10% vs. more than 20% for imatinib and the second-generation tyrosine kinase inhibitors, respectively). In addition, each tyrosine kinase inhibitor has a unique side-effect profile (see Table 170-1). The tyrosine kinase inhibitors tend to be "cross-tolerant" in that if a patient must change the tyrosine kinase inhibitor because of a particular side effect, it is unlikely that the same complication would be found with another tyrosine kinase inhibitor. Chronic fatigue (mostly correlated with musculoskeletal pain and muscular cramps) is especially problematic for imatinib users and is the side effect that most affects quality of life, although fluid retention is also a problem. Pleural effusion is an adverse event for dasatinib and can be found in about 20% of patients (as opposed to 1% with imatinib). In addition, reversible pulmonary arterial hypertension is a rare (about 5%) but serious side effect with dasatinib. Nilotinib can cause a prolongation of the QT interval and is associated with an increased risk for peripheral arterial occlusive disease. Bosutinib's primary toxicity is diarrhea, which can occur in up to 70% of patients. Ponatinib has a strong association with hypertension and carries a black box warning regarding hepatotoxicity and vascular occlusion. Indeed, arterial and venous thrombosis and occlusions occurred in approximately 30% of CML patients receiving the drug who had highly resistant disease, and these events happened in cases with and without cardiovascular risk factors. Peripheral and

TABLE 170-1 THERAPY OF CHRONIC MYELOID LEUKEMIA WITH OUTCOMES AND MOST FREQUENT SIDE EFFECTS

SETTING	DRUGS	CCyR (%)	SURVIVAL (%)	NOTABLE SIDE EFFECTS (TOP THREE)
Frontline	Imatinib	65% at 5 years	83% at 11 years	Muscle spasms (41%), edema (37%), hypophosphatemia (28%)
	Dasatinib	86% at 2 years	91% at 5 years	Neutropenia (29%), pleural effusion (28%), diarrhea (21%)
	Nilotinib	85% at 4 years	94% at 54 months	Rash (38%), headache (32%), fatigue (23%)
	Bosutinib	77% at 1 year	N/A	Diarrhea (70%), increased ALT (23%), thrombocytopenia (14%)
Second/third line	Dasatinib	50% at 5 years	71% at 6 years	
	Nilotinib		85% at 3 years	*For all TKIs given as third-line agents, same side effects occur with higher frequency*
	Bosutinib	40% at 2 years	92% at 2 years	
	Ponatinib	45% at 2 years	90% at 2 years	
	Omacetaxine	10% at 2 years	85% at 2 years	Cytopenias

AP/BC = patients progressing to accelerated phase and blast crisis; bid = twice daily; CCyR = complete cytogenetic remission; DAS = dasatinib; IM = imatinib; MMR = major molecular response; NIL = nilotinib.

coronary occlusion are seen to a lesser degree with bosutinib and are least likely in patients treated with imatinib.

Monitoring Tyrosine Kinase Inhibitor Therapy

The day-to-day management of tyrosine kinase inhibitor side effects is detailed extensively in the National Comprehensive Cancer Network guidelines.[9] The response to therapy must be carefully monitored and assessed. Many studies have shown that peripheral blood quantitative monitoring of mutant *BCR-ABL* transcript by RT-PCR is a sensitive and reliable measure of disease burden and correlates with short-term and long-term outcomes. Because of the exquisite sensitivity of the *BCR-ABL* assay (with an estimated detection limit of 1 CML cell in 10^5 normal cells), peripheral blood testing is the foundation of *monitoring* treatment (www.NCCN.org and www.leukemia-net.org). Indeed, quantitative PCR testing of *BCR-ABL* transcript is recommended as the only monitoring test needed during therapy. Follow-up bone marrow aspirates and cytogenetics are reserved for patients who fail to meet treatment milestones or relapse while on therapy (see later).

A complete hematologic response is the normalization of peripheral blood counts, and it occurs in more than 90% of patients within 3 months of starting tyrosine kinase inhibitor therapy. A cytogenetic response is based on the number of Ph chromosomes found on a metaphase preparation of at least 20 cells. A major cytogenetic response occurs when 0 to 35% of metaphases are positive for Ph chromosomes. A complete cytogenetic response is when no Ph chromosomes are found. Complete cytogenetic response correlates strongly with a high overall survival, and a peripheral blood value *BCR-ABL* allele burden of 1% correlates with a complete cytogenetic response.

A molecular response measures peripheral blood *BCR-ABL* as a ratio to a control (wild-type) gene (*BCR, ABL*, or *GUSB*, depending on the reference laboratory), set to an international scale (IS). A three-log reduction (0.1% IS) is termed a major molecular response and correlates with a superior progression-free survival and overall survival compared with patients with a lesser response. Deeper responses are based on the log reduction in the BCR-ABL load (e.g., MR4 represents a four-log reduction from baseline). The use of the terms "undetectable" and "negative" BCR-ABL is discouraged because the absence of BCR-ABL can be from either low actual disease burden or poor laboratory performance.

Discontinuation of Tyrosine Kinase Inhibitor Therapy

In in vitro studies, the "CML stem cell" appears impervious to tyrosine kinase inhibitor therapy, and therefore it was assumed that patients would have to remain on a tyrosine kinase inhibitor for life because discontinuation would simply allow the stem cell reservoir to proliferate, assuring certain relapse. However, about 40 to 50% of patients who have been without detectable *BCR-ABL* for several years remain in molecular remission for more than 2 years after tyrosine kinase inhibitor therapy is discontinued.[10,11] The minimum pre-discontinuation time appears to be at least 2 years of a deep response. Since about a year is required to obtain a deep response, most patients will have had at least 3 years of therapy. The rapidity of the BCR-ABL decline after initiating therapy ("halving time") and the detection of BCR-ABL by ultrasensitive techniques prior to discontinuation are associated with an increased or decreased chance of treatment-free remission, respectively.[12,13] Most (>90%) relapsing patients respond well and quickly to the reintroduction of therapy, although not all achieve similarly deep responses. Progression to advanced phase disease after discontinuation is exceedingly rare. However, the long-term consequences of discontinuation are unknown, and patients and physicians who wish to try discontinuation are advised to enroll in a clinical trial.

Which Tyrosine Kinase Inhibitor for Frontline Therapy?

Both the National Comprehensive Cancer Network and the European Leukemia Network are agnostic in regard to which tyrosine kinase inhibitor should be used as frontline therapy. Some practical considerations include:

1. *What are the treatment goals?* For an older patient, controlling the disease and extending survival without undue toxicity are primary goals, and these can be accomplished with imatinib. On the other hand, a younger patient may be interested in childbearing and/or discontinuation of tyrosine kinase inhibitor therapy. In this setting, starting with a second-generation tyrosine kinase inhibitor may be the best choice because the likelihood of a deep response is greater.
2. *What is the status of the disease?* Patients who present in chronic phase by morphologic and cytogenetic criteria may be in a high-risk group given a high WBC count and spleen size. In cases in which advancing phase disease is suspected, the use of the more potent second-generation tyrosine kinase inhibitor may have merit.
3. *What is the status of the patient?* Many patients may have comorbidities that can affect drug choice. Of the three agents available, imatinib has the longest track record and seems to be relatively free of long-term side effects. Nilotinib is associated with troublesome side effects in patients with the metabolic syndrome and has a higher incidence of vascular occlusive events compared with imatinib. Dasatinib has the highest risk for producing pleural effusions and is associated with pulmonary artery hypertension in a small subset of patients. Lastly, bosutinib can cause considerable diarrhea.

Resistance to Tyrosine Kinase Inhibition

Primary resistance to imatinib is defined as the failure to normalize peripheral blood counts (which typically occurs 1 to 3 months after initiating therapy). In clinical trials this occurs in less than 10% of cases. This can be confused with poor compliance for reasons noted previously because studies have shown that poor adherence significantly affects the likelihood of patients ever achieving a major molecular response or deeper response, or losing cytogenetic response; they have a nearly 30% chance of losing complete cytogenetic response compared with only about 2% in highly adherent patients. Beyond the strict definition of primary resistance, a failure to reach molecular response milestones

at 3 and 6 months bodes poorly (see later), and the fact that patients with a poor early response have a higher likelihood of early progression to advanced phase disease suggests a biologic relationship between primary resistance and progression.

Acquired or "secondary" resistance describes the phenomenon of an early response to therapy, with subsequent resistance and a rise in *BCR-ABL* transcript levels. In roughly 25 to 50% of cases, this is caused by a single base pair mutation in the *ABL* kinase domain, resulting in a change in protein conformation, with an alteration of the binding of tyrosine kinase inhibitors and the resulting inhibition of *BCR-ABL*. Thus far, more than 100 such mutations have been discovered. It is not clear whether these mutations are present at a very low level even at diagnosis and emerge under the selective pressure of the tyrosine kinase inhibitor, or whether they arise during therapy. In vitro methods have been used to describe the relative inhibitory effects of different tyrosine kinase inhibitors with different mutations, and this can be useful in selecting which tyrosine kinase inhibitor one should use as second-line therapy in cases of resistance. The detection of the T315I mutation is of special note because only one tyrosine kinase inhibitor (ponatinib) is effective with this particular mutation. The T315I mutation becomes more prevalent with increasing patterns of resistance and tyrosine kinase inhibitor substitution, so although unusual at the first signs of resistance, it is quite common in the setting of multiple tyrosine kinase inhibitor failure.

Treatment Milestones for Frontline Therapy in Chronic Phase CML

The National Comprehensive Cancer Network and the European Leukemia Network recommend a set of treatment milestones associated with survival outcomes (Table 170-3). The major prognostic milestones are (1) the achievement of a complete cytogenetic response (or its near equivalent, a *BCR-ABL* of ≤1% IS) should occur by 12 months of therapy; (2) thereafter, achievement of a major molecular response (*BCR-ABL* ≤0.1% IS) is desirable because this level of disease burden is associated with a very low rate of resistance and progression; and (3) deeper responses (MR4.0 and lower) that are sustained may allow for tyrosine kinase inhibitor discontinuation. The failure to reach milestones, or the loss of milestones, should prompt consideration of change to another tyrosine kinase inhibitor and mutation testing to inform the decision of which tyrosine kinase inhibitor to use as second-line therapy.

The treatment response of a complete cytogenetic response at 12 months of tyrosine kinase inhibitor therapy is a prognostic indicator of long-term survival with imatinib or second-generation tyrosine kinase inhibitors. For example, for chronic phase patients receiving either imatinib or second-generation tyrosine kinase inhibitors, the 3-year progression-free survival and overall survival rates for patients with and without a 12-month complete cytogenetic response were 98%/99% and 67%/94%, respectively. Achievement of a major molecular response is associated with continued complete cytogenetic response, less disease progression to advanced phases, and a better overall survival compared with patients without a major molecular response. For example, in the IRIS study, the 10-year overall survival rate was 91% for patients with a major molecular response at 12 months versus 85% in those without a major molecular response. Similar benefits of achieving a major molecular response are seen in patients receiving second-generation tyrosine kinase inhibitors.

Recent attention has shifted to even earlier assessment of disease burden as measured by peripheral blood *BCR-ABL* allele burden at 3 and 6 months of therapy (early molecular response, or EMR). The *BCR-ABL* cutoff of 10% IS or less (good prognosis) versus more than 10% IS (bad prognosis) has been evaluated after frontline therapy with imatinib, dasatinib, and nilotinib, and the early molecular response is consistently associated with short- and long-term outcomes across all tyrosine kinase inhibitors. A retrospective study of chronic phase CML patients treated with imatinib first-line therapy found that patients with 3-month BCR-ABL levels of 10% IS or less had overall survival and progression-free survival rates of 93% (both), whereas patients with more than 10% IS had inferior rates of 57% (both). This trend has been shown in several other retrospective and randomized trials. In addition, cytogenetic and molecular responses also differ based on early molecular response. For example, dasatinib-treated patients with good EMR had a 5-year complete cytogenetic response, a major molecular response, and MR4.5 rates of 94%, 87%, and 54%, whereas patients with poor early molecular response had rates of 41%, 38%, and 5%, respectively.

Second-Line Therapy—Tyrosine Kinase Inhibitors and Other Approaches

For second-line therapy, the second-generation tyrosine kinase inhibitors have quite similar efficacy.[A5,14,15] Single-arm studies suggest that these agents will yield a complete cytogenetic response in 30 to 50% of relapsed cases (much higher in cases in which a tyrosine kinase inhibitor switch was precipitated by a lack of tolerance to the first-line agent). The progression-free survival rate for second-line tyrosine kinase inhibitor therapy is more than 70% (see Table 170-1). At 5-year follow-up, however, only one third of patients remain on treatment. If or when subsequent relapse occurs, a third-line agent can be used, but in this setting, responses are unusual. The possible exception is ponatinib, which in the setting of multiple-resistant or T315I mutations, achieved a complete cytogenetic response of more than 70%, with 2-year progression-free survival rates of about 70%. The more frequent use of ponatinib for resistance has been constrained by its significant vascular side effects, however.

TABLE 170-3 DRUG FAILURE MILESTONES THAT SUGGEST NEED FOR A CHANGE IN TYROSINE KINASE INHIBITOR

TIME POINT AFTER INITIATION OF TKI THERAPY	RESPONSE MILESTONE
3 months	No CHR* Ph+ >95% *BCR-ABL* >10% IS†
6 months	*BCR-ABL* >10% IS Ph+ >35%
12 months	*BCR-ABL* >1% Ph+ >0%
Any time after 12 months	Loss of CHR Loss of CCyR Loss of MMR (*BCR-ABL* >0.1% IS) *ABL* kinase domain mutations New clonal cytogenetic abnormality

*Recommendations for milestones by the National Comprehensive Cancer Network and the European Leukemia Network.

†The National Comprehensive Cancer Network considers change for these patients if the patient has not had treatment interruptions from toxicity or adherence. The European Leukemia Network assesses early molecular response at 6 months.

CCyR = complete cytogenetic response; CHR = complete hematologic response; IS = international scale; MMR = major molecular response; Ph = Philadelphia chromosome; TKI = tyrosine kinase inhibitor.

In heavily pretreated CML patients with resistance to or unacceptable side effects from tyrosine kinase inhibitors, asciminib (10 to 200 mg once or twice daily), an allosteric inhibitor that binds a myristoyl site of the BCR-ABL1 protein, thereby locking BCR-ABL1 into an inactive conformation through a mechanism distinct from all other ABL kinase inhibitors, can provide a major molecular response in about 25 to 50% of patients.[16,A6]

A key question for patients with resistant disease who are placed on a salvage tyrosine kinase inhibitor regimen is when to judge efficacy because allogeneic stem cell transplantation would be the next strategy. Two different studies support an evaluation of response after 3 months of therapy. If a major cytogenetic response is not achieved, the progression-free survival is dramatically different compared with patients achieving a major cytogenetic response. If a patient is a transplantation candidate, a formal search can be initiated at the same time as the initiation of a second-line tyrosine kinase inhibitor because it usually requires 3 months to identify an unrelated donor. Thus, an assessment can be made as to adequacy of tyrosine kinase inhibitor response and availability of a donor at 3 months. If the patient has a good response, tyrosine kinase inhibitor therapy is continued; if the response is poor, the patient can move to transplantation.

Allogeneic Hematopoietic Stem Cell Transplantation

Before the advent of tyrosine kinase inhibitor therapy, allogeneic transplantation was the treatment of choice for newly diagnosed CML. Most centers reported survival rates of 75 to 85%, 25 to 40%, and 10 to 20% for chronic, accelerated, and blast phase disease, respectively. The results are similar for those with related and unrelated matched donors. Currently, transplantation is reserved for salvage therapy for those few patients who cannot tolerate tyrosine kinase inhibitors, patients with highly resistant disease, and those with advanced phase disease.[17,18] Several studies have shown that prior tyrosine kinase inhibitor therapy does not have an adverse effect on transplant-related mortality and that patients who undergo transplantation because of intolerance to tyrosine kinase inhibitors have survival rates similar to untreated historical controls. In additions, studies have shown that patients with T315I mutations have similar outcomes as historical controls.

Who Should Undergo Allogeneic Transplantation in the Era of Tyrosine Kinase Inhibitors?

Reasonable indications might include the following:

1. *Intolerance of tyrosine kinase inhibitors*. Tyrosine kinase inhibitors tend to be cross-tolerant, meaning that if a particular toxicity occurs with tyrosine kinase inhibitor "A," it is unlikely to occur with agent "B." However, rare patients cannot tolerate any tyrosine kinase inhibitors. For these patients, bone marrow transplantation is encouraged.
2. *Primary tyrosine kinase inhibitor failure* (e.g., failure to reach the National Comprehensive Cancer Network or European Leukemia Network guidelines, such as lack of a cytogenetic response by 3 to 6 months, less than major cytogenetic response by 12 months, or complete cytogenetic response by 18 months). These patients should receive a trial of a different tyrosine

kinase inhibitor, but it is prudent to make sure these patients are evaluated for transplantation and undergo HLA typing. Failure of the second agent in this setting would be a reasonable indication at least prompting evaluation for bone marrow transplantation.

3. *Secondary resistance*. When patients become resistant to a frontline agent, the probability of achieving a complete cytogenetic response with a second-line agent is 50% or less. In addition, the probability of such patients failing second-line therapy and developing progression or a T315I mutation is greatly increased compared with tyrosine kinase inhibitor-naïve patients.
4. *Patients with T315I mutation*. Ponatinib is highly effective in chronic phase patients with the T315I mutation, and most patients should initially be started on this agent. However, there is considerable risk for venous and arterial occlusive disease, so patients with a high risk for vascular events or who are young and might need to be on ponatinib for many years should consider the transplantation option. The protein synthesis inhibitor omacetaxine is also approved in this setting, although responses are few and short lived.
5. *Accelerated or blast phase disease*. The rare patients who present with accelerated phase respond well to tyrosine kinase inhibitor therapy and might not need transplantation (although it is worthwhile to begin looking for a donor early in these cases). Patients who present in blast crisis should get intensive therapy (often chemotherapy combined with a tyrosine kinase inhibitor) and move to transplantation when a donor is identified. Patients who progress to advanced phase disease while on a tyrosine kinase inhibitor have a median survival of less than 1 year and need transplantation in short order.
6. *Clonal abnormalities with myelodysplasia*. Clonal changes in Ph chromosome–negative cells occur in about 5% of patients in complete cytogenetic response. In most cases, these do not seem to affect the natural history. However, rare patients have a –5 or –7 abnormality associated with features of myelodysplastic syndrome and should consider bone marrow transplantation.

Treatment of Patients with Advanced Phase CML

It is rare for CML to present in advanced phase disease. Indeed, a patient who presents in lymphoid or myeloid blast crisis is difficult to distinguish from de novo ALL or acute myeloid leukemia (AML; Chapter 163).

Rarely, patients present with advanced phase disease defined by a modest increase in blast counts or the Ph chromosome with other clonal cytogenetic abnormalities. In this case, upfront treatment with a single-agent tyrosine kinase inhibitor regimen is often quite effective, yielding results similar to chronic phase disease. Results are different, however, in chronic phase CML, in which patients who progress to advanced phase disease while on tyrosine kinase inhibitors have a median survival of less than 1 year. Both dasatinib and bosutinib (but not nilotinib) are approved for the treatment of blast phase CML. In general, the blast phase of CML is treated with ALL- or AML-like chemotherapy (Chapter 163), with the addition of a tyrosine kinase inhibitor. Another potentially useful drug approved for chronic and accelerated phase disease is omacetaxine (also known as homoharringtonine), an inhibitor of protein synthesis. The major side effect is myelosuppression, and its role is generally as a bridge to allogeneic transplantation, which is the only potential curative therapy in patients with advanced phase disease in the face of tyrosine kinase inhibitor treatment. The survival rates after allogeneic transplantation are, roughly, for chronic phase more than 80%, accelerated phase 40 to 50%, and blast phase 10 to 20%.

PROGNOSIS

Several clinical and pathologic features at diagnosis or shortly thereafter are associated with long-term response. The strongest prognostic feature is the phase of disease.

Numerous risk scores have been used to predict long-term outcomes. Each combines clinical factors (e.g., age, spleen size) with laboratory values, and all work with a high degree of intrascore system correlation (Table 170-4). The scores typically divide patients into low-, intermediate-, and high-risk categories, with survival and progression correlating with risk group. The Sokal Index, developed in 1984 for chronic phase patients, is the most commonly used and places patients into risk categories based on age, blast count, spleen size, and platelet count. The Hasford score was developed from patients on interferon and adds peripheral blood counts to the Sokal measures. The more recently developed European Treatment and Outcome Study requires only an assessment of the spleen size and percent basophils in blood. All of these scores have online calculators for easy determination of score. At diagnosis, they prove a reasonable guide to predict outcome. These scores work similarly in cases treated with first- and second-generation tyrosine kinase inhibitors alike.

TABLE 170-4 CLINICAL SCORING SYSTEMS USED IN RISK-STRATIFYING CML PATIENTS

	SOKAL	HASFORD	EUTOS
Age	x	x	
Spleen size	x	x	x
Blast (peripheral)	x	x	
Basophilia		x	x
Eosinophilia		x	
Thrombocytosis	x	x	

EUTOS = European Treatment and Outcome Study for CML; Hasford = Hasford score for CML; Sokal = Sokal Index for CML (https://www.mdcalc.com/sokal-index-chronic-myelogenous-leukemia-cml).

Additional Cytogenetic Abnormalities

The presence of major additional chromosomal abnormalities (trisomy 8, isochromosome 17q, second Ph chromosome, and trisomy 19) at diagnosis is generally associated with negative prognostic impact on survival and disease progression to accelerated or blast phase. Patients with major route additional chromosomal abnormalities at the time of diagnosis have longer times to cytogenetic and molecular responses and shorter progression-free survival and overall survival than patients with t(9;22), t(v;22), loss of Y chromosome, or other minor additional chromosomal abnormalities. For example, 5-year survival rates are about 91%, 87%, 89%, 92%, and 52%, respectively, for patients with t(9;22), t(v; 22), loss of Y chromosome, minor route additional chromosomal abnormalities, and major route additional chromosomal abnormalities. Other studies have reported that some of the minor route additional chromosomal abnormalities, such as 11q23 and 3q26 rearrangements, are also associated with poor prognosis. Another study found that the presence of trisomy 8, loss of Y chromosome, or second Ph chromosome had no adverse impact on treatment response and survival, whereas the presence of isochromosome 17q, del7q, or 3q26.2 rearrangements was associated with lower response rates and inferior survival. The concurrent presence of two or more additional chromosomal abnormalities is associated with a poor prognosis.

Next-generation sequencing has shown that chronic phase patients who respond poorly to treatment and who progress to advanced phase disease have a higher prevalence of mutations in genes commonly associated with acute leukemia (e.g., *ASXL1, RUNX1, IZF1*). However, these markers are not currently used in routine clinical treatment algorithms.

Molecular Response

The peripheral blood monitoring of *BCR-ABL* transcripts has a very important role in CML management for the following reasons: (1) the depth of molecular responses is associated with outcomes (the achievement of a major molecular response is a "safe harbor" because disease resistance or progression is extremely rare after this low level of disease burden is achieved); (2) the kinetics of response appears to predict outcome because the rate of achieving the 3-month response is important and patients with a *BCR-ABL* of more than 10% IS at the 3-month mark do poorly compared with patients whose disease recedes more rapidly; and (3) deeper responses, beyond a major molecular response, are becoming increasingly more important as experience, trials, and treatment strategies move toward treatment discontinuation for those patients with a prolonged deep molecular response. Several studies have shown that a proportion of selected patients with persistently undetectable *BCR-ABL*, as defined by at least a 4- or 4.5-log read depth (the so-called "deep molecular response"), may discontinue tyrosine kinase inhibitor therapy without molecular relapse of their disease.

CHRONIC MYELOMONOCYTIC LEUKEMIA AND ATYPICAL CHRONIC MYELOPROLIFERATIVE DISEASES

DEFINITION AND EPIDEMIOLOGY

The chronic non-*BCR-ABL* leukemias are diseases that feature components of both myeloid dysplasia and proliferation. The WHO classifies chronic myelomonocytic leukemia (CMML), juvenile CMML, chronic neutrophilic leukemia (CNL), and atypical CML (aCML) among the myelodysplastic/myeloproliferative disorders (Chapters 152 and 167). Chronic neutrophilic leukemia and atypical CML are poorly named because they do not involve the *BCR-ABL* rearrangement. In CMML, there is an expansion of the monocytic

population in the peripheral blood and bone marrow, whereas in CNL, the neutrophil population is increased.

These diseases are quite rare, and indeed, their incidence is difficult to accurately estimate. CMML is estimated to have an incidence of less than 0.5/100,000, and aCML and CNL are even rarer. The median age at diagnoses for these diseases is approximately 65 to 75 years.

PATHOBIOLOGY

There is no singular distinguishing genetic feature of CMML. Clonal cytogenetic abnormalities are seen in about 30% of cases, and mutations in greater than 90%. The most common mutations are in genes associated with mRNA splicing (e.g., *SF3B1*), cytokine signaling (e.g., *NRAS*), and epigenetic modification (e.g., *TET2*). On the other hand, mutations in *CSF3R* are present in more than 60% of aCML and CNL patients, and this mutation is unusual in other myeloid leukemias and myelodysplastic syndrome. In addition, one fourth of cases of aCML will have a point mutation in the *SETBP1* gene.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Like CML, the signs and symptoms are often nonspecific. The first clue to the diagnosis is usually abnormal peripheral blood WBC counts, which in CMML would demonstrate monocytosis, and may include neutropenia, anemia, and thrombocytopenia. Splenomegaly is quite common in these diseases. The work-up will be negative for the Ph chromosome or molecular evidence of *BCR-ABL*. The bone marrow typically shows myeloid hyperplasia and dysplasia of the myeloid lineage (and sometimes other lineages).[19]

The WHO definition of CMML requires a persistent (at least 3 months) peripheral blood monocytosis of more than 1000/μL and more than 10% of the entire WBC differential. In addition, the peripheral blood and bone marrow myeloblasts plus monoblasts plus promyelocytes must be less than 20% of the total WBC differential; if it is higher, it is classified as AML. Chronic neutrophilic leukemia and atypical CML are not so strictly defined.

TREATMENT AND PROGNOSIS

The median survival for these diseases is less than 3 years, with death arising from either transition to acute leukemia or from complications of cytopenias. There is no curative therapy outside of allogeneic stem cell transplantation.[20] Patients with CMML may benefit from a trial of hypomethylating agents (with an overall response rate of ~30 to 40%) or opt for disease control (if they have a highly proliferative disease) with hydroxyurea under expert supervision.[21] For CMML there is a roughly 20% risk of transformation to acute myeloid leukemia (AML) after 3 years from diagnosis. If transition to AML occurs, induction therapy is often attempted, especially as a bridge to rapid transplantation. In atypical CML and chronic neutrophilic leukemia, mutations in *CSF3R* appear to cause aberrant signaling through SRC or JAK2, depending on where the mutation occurs. Thus, clinical trials are exploring targeted therapy inhibiting SRC and JAK in these rare patients.

171 NON-HODGKIN LYMPHOMAS

JULIE M. VOSE AND JAMES O. ARMITAGE

DEFINITION

Lymphomas are solid tumors of the immune system. Increasing knowledge of the biology of the immune system has led to a corresponding increase in the understanding of these malignancies. In addition to better systems of classification and clinical evaluation, this new knowledge has led to the development of new therapies. Beneficial treatment is available for essentially every patient with non-Hodgkin lymphoma. The overall survival of lymphoma patients has increased steadily over the past 40 years, and many patients can be cured.

EPIDEMIOLOGY

In the United States, an estimated 80,000 or so new cases of non-Hodgkin lymphoma are diagnosed in annually, and about 20,000 patients to die of this disease each year. Non-Hodgkin lymphomas account for about 5% of new cancers in the United States and result in about 3% of cancer deaths. The U.S. lifetime risk for developing non-Hodgkin lymphoma is estimated to be 2.4% (1 in 42) for men and 1.9% (1 in 52) for women.[1] The incidence rate increases dramatically with age and is higher in Whites than in other ethnic groups.

Geographic differences in the incidence of non-Hodgkin lymphomas vary as much as five-fold. The highest rates are seen in the United States, Europe, and Australia, whereas lower rates are seen in Asia. Even more striking are geographic differences in the incidence of certain types of non-Hodgkin lymphoma, such as Burkitt lymphoma, follicular lymphoma, extranodal natural killer (NK)/T-cell nasal lymphoma, and adult T-cell leukemia/lymphoma.

In the United States the incidence rate for non-Hodgkin lymphomas increased by about 3 to 4% yearly from 1950 and the beginning of the 21st century, likely related to increased longevity, to the acquired immunodeficiency syndrome (HIV/AIDS) epidemic (Chapter 353), to occupational and environmental exposures (e.g., agricultural chemicals), to improvements in imaging techniques, and to improvements in the ability of pathologists to diagnose lymphoma. Since then, the incidence rate for non-Hodgkin lymphoma has reached a plateau, and the death rate from the disease has been declining.

PATHOBIOLOGY

For most cases of non-Hodgkin lymphoma, the cause is unknown, although genetic, environmental, and infectious agents have been implicated (Table 171-1).

Genetic Factors

Familial non-Hodgkin lymphoma clusters have been described, with a slightly higher risk for non-Hodgkin lymphoma among siblings and first-degree relatives of patients with lymphoma or other hematologic malignancies. The incidence of non-Hodgkin lymphoma has been associated with polymorphisms in a variety of genes related to immunity, including chemokines, tumor necrosis factor, interleukin-10 (IL-10), and lymphotoxin-α. Polymorphisms in other genes related to the cell cycle and apoptosis have also been associated with an increased risk for developing lymphoma.

Immune System Abnormalities

Several inherited disorders increase the risk for developing non-Hodgkin lymphoma as much as 250-fold (see Table 171-1). In some of these conditions, the lymphoma may be related to Epstein-Barr virus (Chapter 348). For example, patients with X-linked lymphoproliferative disorder have mutations in the *SH2D1A* gene, which encodes proteins that regulate the host immune response against Epstein-Barr virus–infected cells; individuals with this disorder may develop fatal infectious mononucleosis or non-Hodgkin lymphoma after primary exposure to Epstein-Barr virus. Acquired immunodeficiency states are also associated with an increased risk for non-Hodgkin lymphoma. For example, post-transplantation lymphoproliferative disorders (Chapter 348) occur in as many as 20% of solid organ transplant recipients, related to the proliferation of B lymphocytes that have been transformed during immunosuppressive therapy. The risk for non-Hodgkin lymphoma is also increased more than 100-fold in patients infected with the human immunodeficiency virus (HIV, Chapter 355). Almost all central nervous system (CNS) lymphomas

population in the peripheral blood and bone marrow, whereas in CNL, the neutrophil population is increased.

These diseases are quite rare, and indeed, their incidence is difficult to accurately estimate. CMML is estimated to have an incidence of less than 0.5/100,000, and aCML and CNL are even rarer. The median age at diagnoses for these diseases is approximately 65 to 75 years.

PATHOBIOLOGY

There is no singular distinguishing genetic feature of CMML. Clonal cytogenetic abnormalities are seen in about 30% of cases, and mutations in greater than 90%. The most common mutations are in genes associated with mRNA splicing (e.g., *SF3B1*), cytokine signaling (e.g., *NRAS*), and epigenetic modification (e.g., *TET2*). On the other hand, mutations in *CSF3R* are present in more than 60% of aCML and CNL patients, and this mutation is unusual in other myeloid leukemias and myelodysplastic syndrome. In addition, one fourth of cases of aCML will have a point mutation in the *SETBP1* gene.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Like CML, the signs and symptoms are often nonspecific. The first clue to the diagnosis is usually abnormal peripheral blood WBC counts, which in CMML would demonstrate monocytosis, and may include neutropenia, anemia, and thrombocytopenia. Splenomegaly is quite common in these diseases. The work-up will be negative for the Ph chromosome or molecular evidence of *BCR-ABL*. The bone marrow typically shows myeloid hyperplasia and dysplasia of the myeloid lineage (and sometimes other lineages).[19]

The WHO definition of CMML requires a persistent (at least 3 months) peripheral blood monocytosis of more than 1000/μL and more than 10% of the entire WBC differential. In addition, the peripheral blood and bone marrow myeloblasts plus monoblasts plus promyelocytes must be less than 20% of the total WBC differential; if it is higher, it is classified as AML. Chronic neutrophilic leukemia and atypical CML are not so strictly defined.

TREATMENT AND PROGNOSIS

The median survival for these diseases is less than 3 years, with death arising from either transition to acute leukemia or from complications of cytopenias. There is no curative therapy outside of allogeneic stem cell transplantation.[20] Patients with CMML may benefit from a trial of hypomethylating agents (with an overall response rate of ~30 to 40%) or opt for disease control (if they have a highly proliferative disease) with hydroxyurea under expert supervision.[21] For CMML there is a roughly 20% risk of transformation to acute myeloid leukemia (AML) after 3 years from diagnosis. If transition to AML occurs, induction therapy is often attempted, especially as a bridge to rapid transplantation. In atypical CML and chronic neutrophilic leukemia, mutations in *CSF3R* appear to cause aberrant signaling through SRC or JAK2, depending on where the mutation occurs. Thus, clinical trials are exploring targeted therapy inhibiting SRC and JAK in these rare patients.

171 NON-HODGKIN LYMPHOMAS

JULIE M. VOSE AND JAMES O. ARMITAGE

DEFINITION

Lymphomas are solid tumors of the immune system. Increasing knowledge of the biology of the immune system has led to a corresponding increase in the understanding of these malignancies. In addition to better systems of classification and clinical evaluation, this new knowledge has led to the development of new therapies. Beneficial treatment is available for essentially every patient with non-Hodgkin lymphoma. The overall survival of lymphoma patients has increased steadily over the past 40 years, and many patients can be cured.

EPIDEMIOLOGY

In the United States, an estimated 80,000 or so new cases of non-Hodgkin lymphoma are diagnosed in annually, and about 20,000 patients to die of this disease each year. Non-Hodgkin lymphomas account for about 5% of new cancers in the United States and result in about 3% of cancer deaths. The U.S. lifetime risk for developing non-Hodgkin lymphoma is estimated to be 2.4% (1 in 42) for men and 1.9% (1 in 52) for women.[1] The incidence rate increases dramatically with age and is higher in Whites than in other ethnic groups.

Geographic differences in the incidence of non-Hodgkin lymphomas vary as much as five-fold. The highest rates are seen in the United States, Europe, and Australia, whereas lower rates are seen in Asia. Even more striking are geographic differences in the incidence of certain types of non-Hodgkin lymphoma, such as Burkitt lymphoma, follicular lymphoma, extranodal natural killer (NK)/T-cell nasal lymphoma, and adult T-cell leukemia/lymphoma.

In the United States the incidence rate for non-Hodgkin lymphomas increased by about 3 to 4% yearly from 1950 and the beginning of the 21st century, likely related to increased longevity, to the acquired immunodeficiency syndrome (HIV/AIDS) epidemic (Chapter 353), to occupational and environmental exposures (e.g., agricultural chemicals), to improvements in imaging techniques, and to improvements in the ability of pathologists to diagnose lymphoma. Since then, the incidence rate for non-Hodgkin lymphoma has reached a plateau, and the death rate from the disease has been declining.

PATHOBIOLOGY

For most cases of non-Hodgkin lymphoma, the cause is unknown, although genetic, environmental, and infectious agents have been implicated (Table 171-1).

Genetic Factors

Familial non-Hodgkin lymphoma clusters have been described, with a slightly higher risk for non-Hodgkin lymphoma among siblings and first-degree relatives of patients with lymphoma or other hematologic malignancies. The incidence of non-Hodgkin lymphoma has been associated with polymorphisms in a variety of genes related to immunity, including chemokines, tumor necrosis factor, interleukin-10 (IL-10), and lymphotoxin-α. Polymorphisms in other genes related to the cell cycle and apoptosis have also been associated with an increased risk for developing lymphoma.

Immune System Abnormalities

Several inherited disorders increase the risk for developing non-Hodgkin lymphoma as much as 250-fold (see Table 171-1). In some of these conditions, the lymphoma may be related to Epstein-Barr virus (Chapter 348). For example, patients with X-linked lymphoproliferative disorder have mutations in the *SH2D1A* gene, which encodes proteins that regulate the host immune response against Epstein-Barr virus–infected cells; individuals with this disorder may develop fatal infectious mononucleosis or non-Hodgkin lymphoma after primary exposure to Epstein-Barr virus. Acquired immunodeficiency states are also associated with an increased risk for non-Hodgkin lymphoma. For example, post-transplantation lymphoproliferative disorders (Chapter 348) occur in as many as 20% of solid organ transplant recipients, related to the proliferation of B lymphocytes that have been transformed during immunosuppressive therapy. The risk for non-Hodgkin lymphoma is also increased more than 100-fold in patients infected with the human immunodeficiency virus (HIV, Chapter 355). Almost all central nervous system (CNS) lymphomas

ABSTRACT

The non-Hodgkin lymphomas represent no more than 5% of all new cancers, but they have a disproportionate importance because of the ability of therapy to cure a significant fraction of patients. For this reason, the management of lymphoma requires a meticulous approach to diagnosis and staging. A large number of histologic subtypes of lymphoma are recognized with differing clinical and microscopic appearances. Even when lymphomas appear morphologically similar, they may exhibit significant genetic and molecular heterogeneity. These differences, as well as individual patient differences, have ushered in an era of precision medicine for the treatment of lymphoma, with a large number of new chemotherapy agents, monoclonal antibodies, targeted agents, and immunotherapies. These new agents have improved the survival for many types of lymphoma.

TABLE 171-1 FACTORS ASSOCIATED WITH THE DEVELOPMENT OF NON-HODGKIN LYMPHOMA

Inherited immune disorders
Severe combined immunodeficiency disease
Common variable immunodeficiency disease
Wiskott-Aldrich syndrome
Ataxia-telangiectasia
X-linked lymphoproliferative disorder
Autoimmune lymphoproliferative syndrome
Acquired immune disorders
Solid organ transplantation
Acquired immunodeficiency syndrome (AIDS)
Rheumatoid arthritis and systemic lupus erythematosus
Sjögren syndrome
Hashimoto thyroiditis
Celiac disease
Drug related
Methotrexate for autoimmune disorders
JAK1/2 inhibitor for myelofibrosis
Azathioprine for autoimmune disorders
Anti–tumor necrosis factor agents (e.g., infliximab, adalimumab)
Infectious agents
Epstein-Barr virus
Human T-lymphotropic virus type 1
Human herpesvirus type 8
Hepatitis C virus
Helicobacter pylori
Borrelia burgdorferi
Chlamydia psittaci
Campylobacter jejuni
Coxiella burnetii
Occupational and environmental exposure
Herbicides
Organic solvents
Ultraviolet light
Diet
Smoking

and approximately 50% of other lymphomas in patients with the acquired immunodeficiency syndrome (AIDS) are related to Epstein-Barr virus. Some studies have shown a two-fold increase in the incidence of non-Hodgkin lymphomas among patients with rheumatoid arthritis (Chapter 243), and the risk for marginal zone lymphomas is increased approximately 30- to 40-fold in patients with Sjögren syndrome (Chapter 247). Increases in the incidence of thyroid lymphoma are seen in patients with Hashimoto thyroiditis (Chapter 207). Enteropathy-type T-cell lymphomas are associated with celiac disease (Chapter 126). Patients with the autoimmune lymphoproliferative syndrome, associated with mutations in the *FAS* gene, also appear to be at higher risk for developing lymphoma.

Infectious Agents

Epstein-Barr virus (Chapter 348) is associated with the majority of post-transplantation lymphoproliferative disorders and many HIV/AIDS-associated lymphomas. This viral genome is detectable in more than 95% of cases of endemic Burkitt lymphoma and in approximately 15 to 35% of cases of sporadic Burkitt lymphoma and AIDS-associated lymphomas. This virus is also associated with Epstein-Barr virus-positive diffuse large B-cell lymphoma of elderly people, plasmablastic lymphoma, and extranodal NK/T-cell lymphoma.

The human T-lymphotropic virus type 1 (HTLV-1; Chapter 360) is detectable in virtually all cases of adult T-cell leukemia/lymphoma. The risk for lymphoma is approximately 3% in patients infected with HTLV-1. In endemic areas, up to 50% of all non-Hodgkin lymphomas may be related to HTLV-1.

Human herpesvirus-8 (HHV-8, Kaposi sarcoma–associated herpesvirus; Chapter 359), which is associated with expansion of the B-cell population, is also associated with primary effusion lymphoma (see later) in immunocompromised patients and with multicentric Castleman disease. Patients with primary effusion lymphoma are often coinfected with Epstein-Barr virus.

Epidemiologic evidence has linked hepatitis C virus (Chapter 135) to lymphoplasmacytic lymphoma associated with type II cryoglobulinemia, nodal marginal zone lymphoma, and splenic marginal zone lymphoma. Chronic antigenic stimulation from this virus may lead to the emergence of malignant B-cell clones.

Helicobacter pylori is associated with gastric lymphoma (Chapter 178) of extranodal marginal zone/mucosa-associated lymphoid tissue (MALT). Colonized patients develop gastritis from chronic antigenic stimulation mediated by T cells, which respond to *H. pylori*–specific antigens and emergence of malignant B-cell clones. *Borrelia burgdorferi* (associated with Lyme disease, Chapter 296) has been associated with marginal zone B-cell lymphoma of the skin. Evidence also links *Chlamydia psittaci* (Chapter 294) with ocular adnexal lymphomas, *Campylobacter jejuni* with immunoproliferative small intestinal disease (Chapter 279), and *Coxiella burnetii* with diffuse large B-cell and follicular lymphoma.

Environmental and Occupational Exposure

Agricultural chemicals have been associated with an increased risk for developing non-Hodgkin lymphomas, and the strongest associations involve phenoxy herbicides such as 2,4-dichlorophenoxyacetic acid (2,4-D), which was also a component of Agent Orange. An increased risk has also been associated with ionizing radiation (Chapter 18), organic solvents, and nitrates in drinking water, although contradictory results have been reported. Some studies have also linked non-Hodgkin lymphomas to high-fat diets and ultraviolet radiation (Chapter 18). The risk for non-Hodgkin lymphoma is increased approximately 20-fold after treatment for Hodgkin lymphoma (Chapter 172). Heavy smokers (Chapter 363) have an increased risk for developing follicular lymphoma. Low levels of vitamin D have been associated with increased risk for recurrent lymphoma, as well as poor outcome. Anti–tumor necrosis factor (anti-TNF) agents might be associated with an increased risk for developing lymphoma, particularly hepatosplenic T-cell lymphoma. Breast implants also are associated with the development of anaplastic large cell lymphoma.

Pathology

Non-Hodgkin lymphomas are derived from cells of the immune system at varying stages of differentiation. In some cases, the cell of origin is directly linked to the morphology, immunophenotype, and clinical behavior of the lymphoma (E-Fig. 171-1 and Table 171-2).

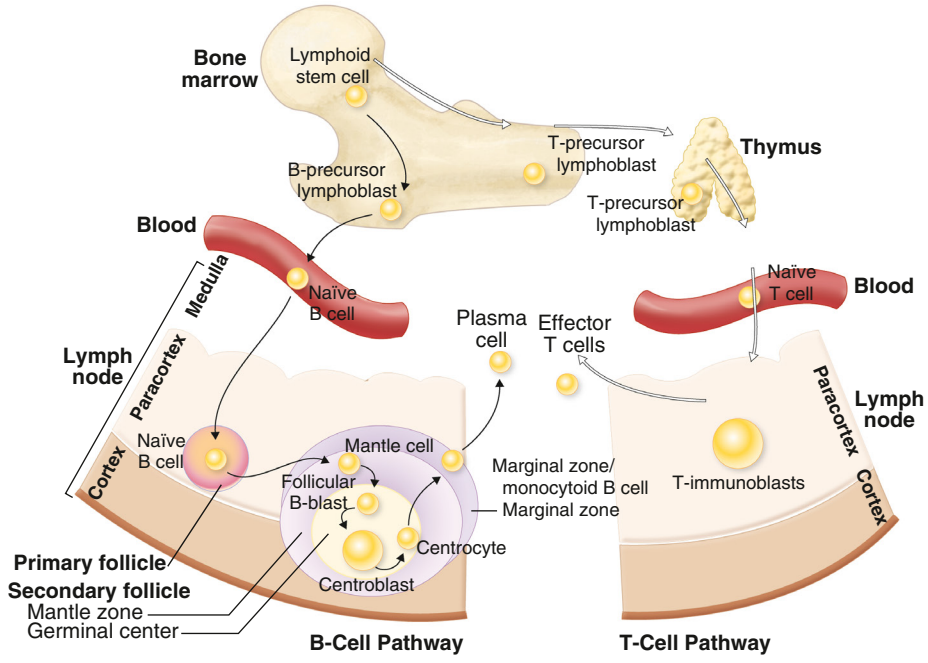
The transformation of cells from the normal immune system into malignant lymphoma reflects the acquisition of specific genetic abnormalities. In many cases, cytogenetic studies can identify chromosomal translocations that underlie the development or progression of the lymphoma. In most cases of non-Hodgkin lymphoma, the activation of proto-oncogenes is the major abnormality, but occasionally chromosomal translocations can lead to fusion genes that code for chimeric proteins. In addition, some cases are associated with deletion of tumor suppressor genes. Specific genetic abnormalities are associated with some specific subtypes of non-Hodgkin lymphoma (Table 171-3). It is becoming clear that the tumor microenvironment from cells of the host immune system is important in tumor cell survival and response to therapy.

Classification

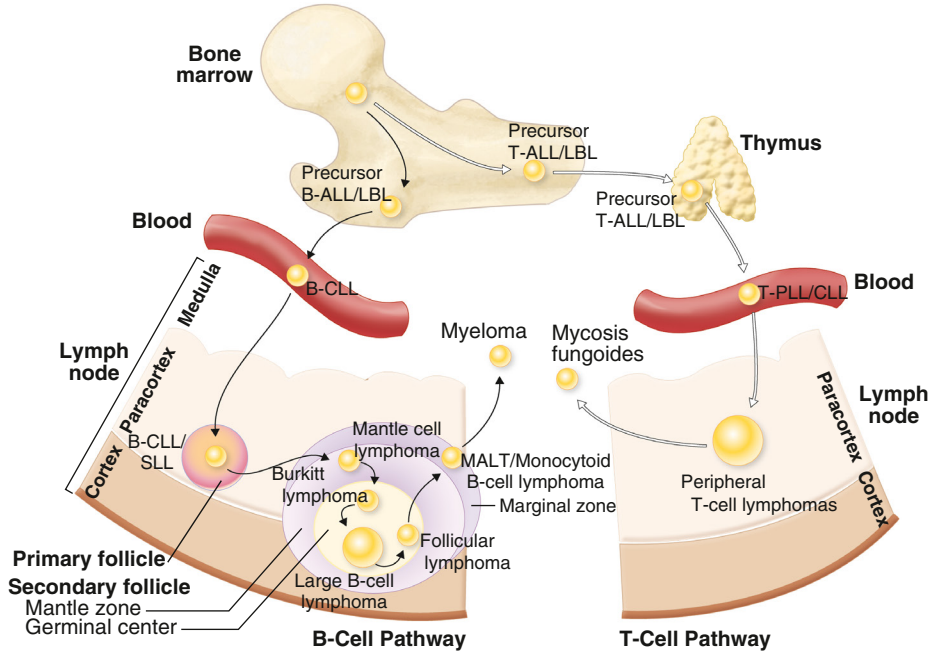
The updated 2016 World Health Organization (WHO) classification integrates genetic data into the clinicopathologic classification (Table 171-4). This classification divides lymphomas on the basis of B-cell or T/NK-cell origin and whether they are derived from primitive precursor cells or from more mature "peripheral" cells. Specific clinical and pathologic entities are recognized within each of these groupings. In the United States and Europe, 85 to 90% of non-Hodgkin lymphomas are B cell in origin.

The most frequent type is diffuse large B-cell lymphoma, which represents about 30% of all non-Hodgkin lymphomas worldwide. The next most frequent type is follicular lymphoma, which represents about 20% of cases. Follicular lymphoma is relatively more frequent in North America and Western Europe and less frequent in Asia. Less common types, each representing between 5 and 10% of all non-Hodgkin lymphomas, are extranodal marginal zone/MALT lymphomas, peripheral T-cell lymphomas, small lymphocytic lymphoma, and mantle cell lymphoma. Other types each represent less than 2% of non-Hodgkin lymphomas seen in the United States.

The non-Hodgkin lymphomas recognized in the WHO classification have clinically distinctive characteristics (Table 171-5), such that an experienced hematopathologist can accurately classify 85% or more of patients by WHO criteria when adequate material is available. Some diagnoses, such as follicular lymphoma, can be made with a high degree of accuracy without immunologic or genetic studies. The diagnosis of T-cell lymphomas cannot be made accurately without immunophenotyping. Cytogenetic studies and molecular genetic studies (fluorescence in situ hybridization, or FISH) can help resolve difficult differential diagnoses. For example, the presence of a t(8;14) translocation supports the diagnosis of Burkitt lymphoma, whereas a t(11;14) with cyclin D1 overexpression can confirm the diagnosis of mantle cell lymphoma (see Tables 171-2 and 171-3).



A



B

E-FIGURE 171-1. Postulated normal counterparts of currently recognized B- and T-cell malignancies. A, Schema of normal B- and T-cell differentiation. Bone marrow–derived lymphoid stem cells differentiate into committed B-cell precursors or into T-cell precursors that undergo further maturation in the thymus. These B- and T-cell precursors mature into naïve B or T cells that circulate to lymph nodes. After antigen exposure, normal B blasts proliferate and undergo further differentiation in the germinal center of the secondary follicle. The germinal center is surrounded by a mantle zone and a marginal zone. Antigen-specific B cells generated in the germinal center leave the follicle and reappear in the marginal zone. Thereafter, immunoglobulin-producing plasma cells accumulate in the lymph node medulla and subsequently exit to the periphery. Antigen-dependent T-cell proliferation occurs in the lymph node paracortex. After antigen exposure, mature T cells become immunoblasts and, subsequently, antigen-specific effector T cells that exit to the periphery. The postulated normal counterparts of many currently recognized T- and B-cell neoplasms are shown. **B,** T- and B-cell malignancies derived from the postulated normal counterparts shown in **A.** ALL = acute lymphoblastic leukemia; CLL = chronic lymphocytic leukemia; LBL = lymphoblastic lymphoma; MALT = mucosa-associated lymphoid tissue; PLL = prolymphocytic leukemia; SLL = small lymphocytic lymphoma.

TABLE 171-2 TYPICAL IMMUNOPHENOTYPES OF COMMON NON-HODGKIN LYMPHOMAS

LYMPHOMA	CD20	CD3	CD10	CD5	CD23	OTHER
Small lymphocytic	+	–	–	+	+

ALK = anaplastic lymphoma kinase; EMA = epithelial membrane antigen; MALT = mucosa-associated lymphoid tissue; TdT = terminal deoxynucleotidyl transferase.

Gene expression profiling has allowed the identification of distinct subsets of patients with diffuse large B-cell lymphoma (DLBCL). Patients with histologically identical lymphomas can be divided into those with gene expression patterns resembling normal germinal center B cells (GCBs), those whose tumors resemble activated post–germinal center B cells (ABCs), or those with patterns resembling that seen in Hodgkin lymphoma. The last pattern is most frequently found in young women who present with large mediastinal masses. Use of immunohistochemistry to subdivide diffuse large B-cell lymphoma into germinal center B cell subtype and activated post–germinal center B cell subtype is widely used but does not correlate perfectly with DNA microarray results. Using a combination of exome and transcriptome sequencing, array-based DNA copy-number analysis, and targeted amplicon resequencing of selected genes, diffuse large B-cell lymphoma can be further subtyped based on shared genomic abnormalities.

CLINICAL MANIFESTATIONS

The most common presentation of non-Hodgkin lymphoma is lymphadenopathy (Fig. 171-1; Chapter 154). In many cases, patients notice cervical, axillary, or inguinal adenopathy and seek a physician's advice. In general, lymph nodes containing lymphomas are firm, nontender, and not associated with a regional infection. In other patients, lymphadenopathy occurring in sites such as the mediastinum or retroperitoneum causes symptoms such as chest pain, cough, abdominal pain, and back pain. More extensive disease can also cause symptoms related to the superior vena cava syndrome, spinal cord compression, and renal insufficiency (associated with ureteral compression).

Non-Hodgkin lymphomas are often associated with systemic symptoms that may lead to the diagnosis. The most obvious symptoms, termed B symptoms, are fever, night sweats, and unexplained weight loss. Any of these symptoms without an obvious cause should lead a physician to consider the diagnosis of lymphoma. Other, less characteristic symptoms include fatigue, which is frequently present at the time of diagnosis if the patient is questioned carefully, and pruritus.

Non-Hodgkin lymphomas can involve essentially any organ in the body, and malfunction of that organ can cause symptoms that lead to the diagnosis. Examples include neurologic symptoms with primary brain lymphoma (Chapter 175), shortness of breath with MALT lymphomas in the lung, epigastric pain and vomiting with gastric MALT lymphomas or diffuse large B-cell lymphomas (Chapter 178), bowel obstruction with small bowel lymphomas (Chapter 179), testicular masses with diffuse large B-cell lymphoma (Chapter 185), and skin lesions with cutaneous lymphomas (Chapter 407). Many lymphomas involve the bone marrow and occasionally cause extensive myelophthisis (Chapter 151) and bone marrow failure. These patients may present with infections, bleeding, and anemia.

Non-Hodgkin lymphomas can also manifest with a variety of immunologic abnormalities. For example, autoimmune hemolytic anemia (Chapter 146) and immune thrombocytopenia (Chapter 158) can be the presenting manifestations of non-Hodgkin lymphoma, especially small lymphocytic lymphoma/chronic lymphocytic leukemia as well as other subtypes, including diffuse large B-cell lymphoma. Peripheral neuropathies (Chapter 388), often associated with overproduction of a monoclonal protein, can be seen in a variety of subtypes but are most characteristic of lymphoplasmacytic lymphoma; sometimes they are also seen with POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes; Chapter 173). Paraneoplastic neurologic complications of non-Hodgkin lymphoma include demyelinating polyneuropathy, Guillain-Barré syndrome, autonomic dysfunction, and peripheral neuropathy. Paraneoplastic syndromes (Chapter 164) associated with non-Hodgkin lymphoma can affect the skin (e.g., pemphigus), kidney (e.g., glomerulonephritis), and miscellaneous organ systems (e.g., vasculitis, dermatomyositis, cholestatic jaundice).

TABLE 171-3 CHROMOSOMAL TRANSLOCATIONS CHARACTERISTIC OF NON-HODGKIN LYMPHOMA

LYMPHOMA SUBTYPE	TRANSLOCATION	GENES INVOLVED	FREQUENCY (%)
Diffuse large B cell	t(3q27) t(14;18)(q32;q21) t(18;14)(q24;q32)	*BCL6* *IgH, BCL2* *MYC (c-Myc), IgH*	35 15-20 <5

ALCL = anaplastic large cell lymphoma; ALK = anaplastic lymphoma kinase; MALT = mucosa-associated lymphoid tissue.

DIAGNOSIS

Each new patient with a non-Hodgkin lymphoma should be thoroughly evaluated in a systematic manner (Table 171-6). The diagnosis of non-Hodgkin lymphoma must be considered in patients with compatible clinical presentations and then confirmed by an adequate biopsy read by an experienced hematopathologist. The diagnosis should never be inferred, and patients should not be treated until the diagnosis is confirmed by biopsy. Similarly, patients who achieve a complete remission with initial therapy should not be treated for presumed relapse on the basis of symptoms or abnormal images without a biopsy. Because subtle pathologic distinctions may alter therapy, the most important issue in managing non-Hodgkin lymphoma is to establish an accurate diagnosis.

The differential diagnosis in patients with non-Hodgkin lymphoma is broad. Any cause of lymphadenopathy or splenomegaly can potentially be confused with non-Hodgkin lymphoma (Chapter 154).[2] However, this confusion is resolved by an appropriate biopsy. Core needle biopsies can occasionally be used for a primary diagnosis if the specimen is handled properly. Fine-needle aspirates should not be used to diagnose lymphoma, because they preclude an accurate diagnosis of the specific subtype of non-Hodgkin lymphoma. In most cases, an excisional biopsy is necessary (and is always preferred) for the

TABLE 171-4 2016 REVISION OF THE WHO CLASSIFICATION OF NON-HODGKIN LYMPHOMA

MATURE B-CELL NEOPLASMS
Chronic lymphocytic leukemia/small lymphocytic lymphoma

This table does not include the lymphoid leukemias, plasma cell dyscrasia, and Hodgkin lymphoma (see Chapter 172).

Modified from Swerdlow SH, Campo E, Pileri SA, et al. The 2016 revision of the World Health Organization classification of lymphoid neoplasms. *Blood* 2016;127:2375-2390.

initial diagnosis. A second biopsy should be performed if sufficient material is not obtained with the first attempt.

Staging and Prognostic Systems

After diagnosis, a meticulous staging evaluation is necessary to estimate prognosis and determine therapy. Staging requires a careful history and physical examination; complete blood count; renal and hepatic function tests; serum lactate dehydrogenase (LDH) level; either computed tomography (CT) of the chest, abdomen, and pelvis or positron emission tomography (PET), which can often replace CT scanning when done on a combined PET/CT machine; and bone marrow biopsy (might not be necessary in patients with diffuse large B-cell lymphoma if the PET/CT scan showed bone marrow involvement). PET can identify initial sites of involvement and, after treatment, can distinguish persisting lymphoma from residual fibrosis in masses seen on CT. The most common staging system is the Ann Arbor classification, which separates patients into four stages based on anatomic sites of disease (Table 171-7). In addition, each stage is subdivided into A (no defined general symptoms) and B (unexplained weight loss >10% of body weight in the previous 6 months, unexplained temperature >38° C, or night sweats) categories. Known sites of disease can be re-evaluated after treatment to evaluate the response to therapy.

Although a wide variety of patient factors (e.g., age, symptoms, LDH level) and tumor factors (e.g., bulk, gene expression pattern, proliferation rate) can affect treatment outcomes, two prognostic systems can help in choosing therapy and determining an accurate prognosis. The International Prognostic Index (Table 171-8) is the most widely used method to predict treatment outcome and survival. This index is based on five adverse factors (age >60 years, performance status ≤2, elevated serum LDH level, two or more extranodal sites of disease, Ann Arbor stage III or IV), which are summed to give the score. This index was developed for patients with diffuse aggressive lymphoma (predominantly diffuse large B-cell lymphoma), but it can be used to predict treatment outcome with any subtype. For patients younger than 60 years, an abbreviated index that uses only reduced performance status, elevated serum LDH level, and high stage can be applied. Because patients with follicular lymphoma rarely have a reduced performance status or a large number of extranodal sites, an alternative index termed the Follicular Lymphoma International Prognostic Index was developed. It substitutes more than four nodal areas of involvement and a hemoglobin value less than 12 g/dL as staging criteria and is better for predicting the outcome of treatment for follicular lymphoma.

At the end of therapy, patients should undergo restaging, which involves repeating previously abnormal tests to prove the patient has achieved a complete remission. For most subtypes of lymphoma, the best definition of a complete remission is a PET/CT scan that has a score of Deauville 1, 2, or 3. The Deauville score uses the intensity of uptake in the mediastinum and liver as an internal control and is the most widely used system for documenting remission (Table 171-9).

TREATMENT

Lymphomas may behave in an indolent or an aggressive manner. The behavior of many of these neoplasms is distinctive, but within each category, behavior is frequently influenced by disease site, tumor bulk, and performance status of the patient. Some lymphomas can be managed, at least initially, with observation, whereas other situations are medical emergencies, such as spinal cord compression. Three questions should be considered before starting therapy: (1) Does treatment have curative potential? (2) Can treatment prolong survival? (3) Will treatment alleviate symptoms? When treatment is appropriate, genomic profiling is typically recommended to guide therapy and inform prognosis.[3]

SPECIFIC TYPES OF NON-HODGKIN LYMPHOMAS

PRECURSOR T-CELL AND B-CELL LYMPHOMAS

Precursor T-cell and B-cell lymphomas are nodal or other solid tissue infiltrates of cells that are morphologically and immunophenotypically identical to the immature cells seen in B-cell or T-cell acute lymphoblastic leukemia (Chapter 168). Patients who have predominantly nodal disease with minimal or no involvement of the bone marrow are frequently classified as having *lymphoblastic lymphoma*, whereas those with more than 25% neoplastic cells in the marrow are classified as having *lymphoblastic leukemia*. These distinctions are arbitrary and reflect the stage of disease rather than different diagnoses. These neoplasms are more common in children than in adults.

TABLE 171-5 PRESENTING CLINICAL CHARACTERISTICS OF COMMON NON-HODGKIN LYMPHOMA SUBTYPES

TYPE OF LYMPHOMA	MEDIAN AGE (yr)	MALE (%)	STAGE (%) I	STAGE (%) IV	B SYMPTOMS (%)	BONE MARROW INVOLVED (%)
B-CELL LYMPHOMAS						
Small lymphocytic	65	53	4	83	33	72
Lymphoplasmacytic	63	53	7	73	13	73
Extranodal marginal zone MALT	60	48	39	31	19	14
Nodal marginal zone	58	42	13	40	37	32
Follicular	59	42	18	51	28	42
Mantle cell	63	74	13	71	28	64
Diffuse large B cell	64	55	25	33	33	16
Mediastinal large B cell	37	34	10	31	38	3
Burkitt	31	89	37	38	22	33
PRECURSOR B/T-CELL LYMPHOMAS						
Precursor T lymphoblastic	28	64	0	75	21	50
T-CELL LYMPHOMAS						
Anaplastic large T cell	34	69	19	39	53	13
Peripheral T cell, NOS	61	55	8	65	50	36

B symptoms = fevers, night sweats, and weight loss; MALT = mucosa-associated lymphoid tissue; NOS = not otherwise specified.

FIGURE 171-1. Non-Hodgkin lymphoma. Despite the redness of the skin over the enlarged lymph node in this patient, the lesion was completely painless. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

TABLE 171-7 STAGING OF NON-HODGKIN LYMPHOMA

STAGE	DESCRIPTION
I	Involvement of a single lymph node region (I) or a single extralymphatic organ or site (I_E)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and one or more lymph node regions on the same side of the diaphragm (II_E)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by localized involvement of an extralymphatic organ or site (III_E) or by involvement of the spleen (III_S) or both (III_{SE})
IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node enlargement
Subtypes	
A	No B symptoms
B	B symptoms: unexplained weight loss ≥10% of body weight in prior 6 months, unexplained fever with temperature >38° C, or night sweats

TABLE 171-6 TYPICAL EVALUATION OF A PATIENT NEWLY DIAGNOSED WITH NON-HODGKIN LYMPHOMA

1. Biopsy to establish diagnosis
2. Careful history and physical examination
3. Laboratory evaluation
   - A. Complete blood count
   - B. Chemistry screen, including lactate dehydrogenase
4. Imaging studies
   - A. Computed tomography (CT) of chest, abdomen, and pelvis
   - B. Positron emission tomography (can often replace the CT scan)
5. Additional biopsies
   - A. Bone marrow
   - B. Any other suspicious site if results would change therapy (i.e., lumbar puncture)

B-cell precursor lymphomas frequently manifest as solid tumors with involvement of the skin and bones, whereas T-cell neoplasms typically manifest as a mediastinal mass in young males. Involvement of the CNS is common in T-cell lymphomas. Approximately 90% of patients who present with lymphoblastic lymphoma have a T-cell phenotype, whereas about 85% of patients who present with acute lymphoblastic leukemia have a B-cell phenotype.

TREATMENT AND PROGNOSIS

Patients with either T-cell lymphoblastic lymphoma or precursor B-cell lymphoblastic lymphoma are typically treated with regimens modeled after those used for acute lymphoblastic leukemia (Chapter 168). These regimens frequently contain cytarabine and high-dose methotrexate, and they often include maintenance therapy. CNS prophylaxis with intrathecal chemotherapy, high-dose methotrexate, or cranial irradiation is often a component of these regimens. Adverse prognostic characteristics include CNS involvement, stage IV disease, and an elevated LDH level.

TABLE 171-8 INTERNATIONAL PROGNOSTIC INDEX

TABLE 171-9 THE DEAUVILLE SCORE FOR ASSESSING POSITRON EMISSION TOMOGRAPHY/COMPUTED TOMOGRAPHIC SCANS TO MEASURE PATIENT RESPONSES TO THERAPY

CRITERIA

1. No uptake related to lymphoma
2. The highest uptake in any site of lymphoma is less than or equal to to the uptake by the mediastinum
3. The highest uptake by any site of lymphoma is greater than the uptake by the mediastinum, but less than or equal to the uptake by the liver
4. The uptake by any site of lymphoma is greater than the uptake by the liver
5. The presence of new sites of uptake or substantial increases in the standardized uptake value in previous sites of lymphoma, or both

MATURE B-CELL LYMPHOMAS

SMALL LYMPHOCYTIC LYMPHOMA AND CHRONIC LYMPHOCYTIC LEUKEMIA

Small lymphocytic lymphoma is defined as a lymph node or other tissue infiltrate that is morphologically and immunophenotypically identical to chronic lymphocytic leukemia (Chapter 169). Patients frequently are symptom free, and the diagnosis is often made when blood counts are performed for other reasons. Patients frequently have lymphadenopathy or splenomegaly. Fatigue is common. Hypogammaglobulinemia can occur and may lead to an increased susceptibility to infection.

TREATMENT AND PROGNOSIS

The median survival time is more than 10 years for patients without adverse characteristics, and these patients often can be managed initially with observation. Therapy is necessary for patients who develop extreme fatigue or have systemic symptoms, for those with rapidly progressive or symptomatic lymphadenopathy or splenomegaly, and for those who develop cytopenias. Management (Chapter 169) must be individualized because therapy is unlikely to be curative, and patients are often elderly.[4] Allogeneic hematopoietic stem cell transplantation may be curative, but few patients are candidates for this approach. Patients may develop autoimmune thrombocytopenia (Chapter 158), autoimmune neutropenia (Chapter 153), and red blood cell aplasia (Chapter 151). These disorders may respond to treatment with corticosteroids, intravenous immune globulin, anti-CD20 monoclonal antibodies such as rituximab or obinutuzumab, cyclosporine, or splenectomy, as used in patients without underlying lymphoma.

A poor prognosis is associated with advanced stage and systemic symptoms, unmutated immunoglobulin heavy chain genes, and genetic abnormalities such as del(17p) or *TP53* mutation. As many as 10% of patients exhibit transformation to diffuse large B-cell lymphoma (Richter syndrome), which is associated with a poor prognosis.

EXTRANODAL MARGINAL ZONE LYMPHOMA OF MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT LYMPHOMA)

The WHO classification of lymphomas recognizes three groups of marginal zone lymphomas (MZL): (1) splenic MZL, (2) nodal MZL, and (3) extranodal MZL of the MALT type (MALT lymphoma).[5] The marginal zone B cells in general are continuously exposed to exogenous antigens and have a physiologically reduced threshold for triggering proliferation, which may predispose them to malignant transformation. The first two types of marginal zone lymphomas are discussed later (section on "Rare Types of B-Cell Lymphoma"). They have different diagnostic criteria, behavior, and therapeutic implications.

MALT lymphomas are indolent lymphomas that originate in association with epithelial cells and are seen most commonly in the gastrointestinal tract, salivary glands, breast, thyroid, orbit, conjunctiva, skin, and lung. Gastric MALT lymphomas are frequently associated with infection by *H. pylori* (Chapter 125). The majority of cases are stage I or II at diagnosis, although in some series as many as 30% disseminate to bone marrow or other sites. These lymphomas tend to remain localized for extended periods.

TREATMENT AND PROGNOSIS

Local treatment with surgery or radiation therapy cures a high proportion of localized neoplasms. Even in patients who have more than one extranodal site, locations can sometimes be successfully treated with local therapy. Patients without symptoms can be monitored closely without therapy until symptoms progress. Patients with symptoms can be treated with rituximab, single-agent chemotherapy, or combinations similar to the treatment of follicular lymphoma (see later).[6]

About 75% of patients with gastric MALT lymphomas achieve remission after eradication of *H. pylori* (see Chapter 125), and more than 90% remain in remission for prolonged periods of time. Nonresponders are more likely to have submucosal invasion by endoscopic ultrasonography, lymph node metastases, or the t(11;18) chromosomal translocation. Approximately 25% of patients progress, of whom about 25% develop diffuse large B-cell lymphoma. Gastric MALT lymphoma that does not respond to antibiotics can be treated with radiation, rituximab as a single agent (similar to its use in follicular lymphoma), or several traditional combination chemotherapy regimens (see Table 171-10).

FOLLICULAR LYMPHOMA

Follicular lymphoma is derived from germinal center B cells. The hallmark t(14;18)(q32;q21) translocation of follicular lymphomas occurs early in B-cell development, caused by an error in VDJ ("variable," "diversity," and "joining" gene segments) recombination.[7] Follicular lymphoma is the most frequent of indolent or low-grade lymphomas in the United States. Follicular lymphoma is divided into three grades based on the proportion of large, transformed cells (centroblasts).

Patients with follicular lymphoma are frequently asymptomatic. The most common presenting complaint is painless lymphadenopathy. Some patients have cough or dyspnea related to pulmonary or mediastinal involvement or pleural effusions. Other patients have symptoms of abdominal pain or fullness related to subdiaphragmatic or splenic disease. A minority of patients have systemic symptoms of fevers, night sweats, or weight loss.

The clinical behavior and treatment of follicular lymphoma grades 1 and 2 are the same. Some grade 3 follicular lymphomas have a more aggressive clinical course and are treated similarly to diffuse large B-cell lymphoma (see later). This distinction between grade 3a (indolent behavior) and 3b (aggressive behavior) is based on the presence or absence of sheets of centroblasts, although this separation may not be reproducible among pathologists.

TREATMENT AND PROGNOSIS

Watch and Wait

A "watch and wait" approach is reasonable in asymptomatic elderly patients, patients with other medical illnesses, and in other selected patients who have low-grade follicular lymphoma and who are asymptomatic, have no disease involvement in sites that might be dangerous, and desire to avoid therapy as long as possible.[8] Such patients can sometimes be observed for long periods before treatment is required. However, modern treatment options may improve the survival of a large proportion of patients with follicular lymphoma.

TABLE 171-10 COMBINATION CHEMOTHERAPY REGIMENS FOR NON-HODGKIN LYMPHOMA

REGIMEN	DOSE	DAYS OF ADMINISTRATION	FREQUENCY
R-CHOP			**EVERY 21 DAYS**
Cyclophosphamide	750 mg/m^2 IV	1	
Doxorubicin	50 mg/m^2 IV	1	
Vincristine	1.4 mg/m^2 IV*	1	
Prednisone, fixed dose	100 mg daily PO	1-5	
Rituximab	375 mg/m^2 IV	1	
R-EPOCH†			**EVERY 21 DAYS**
Etoposide	50 mg/m^2/day IV‡	1-4	
Doxorubicin	10 mg/m^2/day IV‡	1-4	
Vincristine	0.4 mg/m^2/day IV‡	1-4	
Cyclophosphamide	750 mg/m^2 IV	5	
Prednisone	60 mg/m^2 bid PO	1-5	
Rituximab	375 mg/m^2 IV	1	
R-CVP			**EVERY 21 DAYS**
Cyclophosphamide	1000 mg/m^2 IV	1	
Vincristine	1.4 mg/m^2 IV*	1	
Prednisone, fixed dose	100 mg daily PO	1-5	
Rituximab	375 mg/m^2 IV	1	
B-R			**EVERY 28 DAYS**
Bendamustine	90 mg/m^2/day IV	1-2	
Rituximab	375 mg/m^2 IV	1	

*Vincristine dose is often capped at 2 mg total.
†Doses are adjusted based on myelosuppression with previous cycle.
‡Continuous infusion.
bid = twice daily; IV = intravenous; PO = oral.

Localized Disease

Approximately 5 to 15% of patients have localized disease (stage I or minimal stage II disease) at diagnosis. These lymphomas are typically treated with involved-field radiation, preferably with 24 Gy in 12 equal fractions,[A1] and most series report 10-year disease-free survival rates of approximately 50% and overall survival rates of about 50% at 20 years.[9]

Advanced Disease

Most patients with follicular lymphoma have extensive disease at diagnosis. The median survival time of these patients has improved after the addition of rituximab and is now 10 to 20 years. Spontaneous regression also has been described. However, as many as 30 to 50% of patients experience transformation to a more aggressive histology—usually diffuse large B-cell lymphoma. Transformation is frequently associated with new systemic symptoms, rapidly progressive lymphadenopathy, an aggressive clinical course, and a poor prognosis.

Most patients with follicular lymphoma eventually require treatment because of systemic symptoms, symptomatic or progressive lymphadenopathy, splenomegaly, effusions, or cytopenias. In elderly patients, patients who are poor candidates for intensive chemotherapy regimens, and patients who want to avoid the side effects of chemotherapy, single-agent rituximab (375 mg/m^2 intravenously, given weekly for 4 consecutive weeks) yields an objective response rate of well over 50%. The median duration of response is approximately 1 to 2 years for patients who receive no additional therapy, but the response can be extended with ongoing administration of rituximab once every 2 or 3 months or by repeating the initial four doses every 6 months.[10] When rituximab is combined with standard chemotherapy regimens (see Table 171-10) or with lenalidomide, the response rate, duration of response, and survival are increased compared with the chemotherapy regimen alone.[A2,A3] Maintenance rituximab extends the duration of remission but not overall survival.[A4] An alternative is obinutuzumab, which can provide longer progression-free survival but at the expense of more side effects, without improving overall survival.[A5]

Salvage Therapy

Most patients respond to initial chemotherapy. However, follicular lymphoma recurs in the majority of patients with advanced-stage disease. Patients who relapse usually respond to additional therapy, sometimes with the same agents, although the duration of response becomes progressively shorter with repeated courses of therapy.[11] For patients with disease that is refractory to rituximab, the combination of obinutuzumab plus bendamustine is preferable to bendamustine alone.[A6] Copanlisib, which is a pan-class PI3K inhibitor has also shown promising results when added to rituximab.[A7] Alternative therapies include lenalidomide with rituximab, or standard chemotherapies. Radiation therapy also may be useful for patients with a localized site of symptomatic disease.

Prolonged remissions have been observed after autologous hematopoietic stem cell transplantation. Allogeneic hematopoietic stem cell transplantation may cure some patients with relapsed follicular lymphoma but has more toxicity than autologous transplants. Chimeric antigen receptor (CAR) T-cell therapy (Chapter 164) has shown promise as salvage therapy in patients with relapsed or refractory B-cell lymphomas and is now FDA approved for patients whose follicular lymphoma has failed two prior therapies.[12]

MANTLE CELL LYMPHOMA

Mantle cell lymphoma is a B-cell neoplasm composed of small lymphoid cells that may resemble small lymphocytic lymphoma or follicular lymphoma. It is most common in elderly patients and is usually at an advanced stage at the time of diagnosis. Males are more frequently affected, and extranodal disease, especially involvement of the bone marrow, Waldeyer ring, and the gastrointestinal tract, is common. Mantle cell lymphoma is the most common cause of multiple lymphomatous polyposis, and many oncologists recommend that the gastrointestinal tract be evaluated with endoscopy during the initial evaluation.

Some patients present with involvement of the peripheral blood as well as the bone marrow, a clinical picture that resembles chronic lymphocytic leukemia (Chapter 169). The lymphocytes in both disorders are CD5$^+$, but the t(11;14) translocation[13] and overexpression of cyclin D1 seen in mantle cell lymphoma usually allow an accurate diagnosis.

TREATMENT AND PROGNOSIS

Occasional patients, particularly patients with a leukemic presentation, may have an indolent course without initial therapy. However, the median survival of mantle cell lymphoma has significantly improved with new therapies.[14] The combination of bendamustine plus rituximab and regimens that incorporate high-dose cytarabine are efficacious, as is the combination of lenalidomide plus rituximab. Ibrutinib added to rituximab plus bendamustine can significantly prolong remission-free survival[A8] and is commonly part of standard therapy. Substituting bortezomib (1.3 mg/m^2 on days 1, 4, 8, and 11) for vincristine (VR-CAP rather than R-CHOP) can improve the median progression-free survival seen with R-CHOP alone by about 40% (from 14 to about 25 months) in newly diagnosed patients.[A9] Maintenance rituximab seems to prolong the duration of remission.

Autologous hematopoietic stem cell transplantation is widely used for patients in their first remission. The Bruton tyrosine kinase inhibitors such as ibrutinib or acalabrutinib are very active and are part of standard therapy for relapsed disease.[15] If such therapy is not successful, anti-CD19 CAR T-cell therapy may provide a complete response in about 60% of patients.[16] Allogeneic transplantation can be curative but is associated with considerable morbidity and mortality.

The elderly comprise the majority of the patients with mantle cell lymphoma. For patients who are not too frail, 4-year overall survival of greater than 80% can be achieved with rituximab and moderate intensive chemotherapy such as R-CHOP followed by rituximab maintenance or R-bendamustine.

DIFFUSE LARGE B-CELL LYMPHOMA

Diffuse large B-cell lymphomas are the most common type of non-Hodgkin lymphoma, but their morphology and genetic features are heterogeneous. Signs and symptoms are similar to those of other subtypes, although patients are more likely to have B symptoms.[17]

The 2016 WHO classification of non-Hodgkin lymphomas has identified several variants and subtypes of diffuse large B-cell lymphoma (see Table 171-4). Many of these histologic or genetic subtypes or variants share the same standard treatment approach as used for diffuse large B-cell lymphoma. Other subtypes present unusual clinical syndromes or specific therapeutic problems.

TREATMENT

Localized Disease

As many as 30% of patients with diffuse large B-cell lymphoma have stage I or minimal stage II disease. These patients are occasionally cured with radiation therapy alone, but initial treatment with chemotherapy alone or combined with radiation therapy is more effective.[18] In the United States, most patients are treated with R-CHOP (see Table 171-10). Some patients can be treated with fewer courses of chemotherapy if radiotherapy is included. For patients with bulky disease, a complete course of chemotherapy is usually used with or without radiotherapy. Some physicians advocate the use of PET scans to shorten the duration of therapy or eliminate the need for radiotherapy in complete responders.

Advanced Disease

R-CHOP is still the most widely used regimen for adults of all ages with advanced-stage diffuse large B-cell lymphoma. Among patients older than age 60 years, 75% achieve a complete response, with a 10-year progression-free survival rate of about 35% and a 10-year overall survival rate of about 45%. In younger patients, the outcome is better. No advantage has been found for R-EPOCH over R-CHOP (see Table 171-10).[A10] Autologous stem cell transplantation in first remission may benefit very high-risk patients. Although not yet FDA approved for this purpose, the antibody-drug conjugate polatuzumab vedotin combined with R-CHP (rituximab-cyclophosphamide-doxorubicin-prednisone) can improve progression-free survival of diffuse large B-cell lymphoma patients compared with R-CHOP.[A11]

Salvage Therapy

A variety of chemotherapy regimens for patients who relapse after attaining a remission with initial chemotherapy commonly contain agents such as cisplatin, cytarabine, etoposide, carboplatin, and ifosfamide. Response rates exceeding 50% can be observed with these combinations, although no more than 10% of patients achieve long-term disease-free survival. High-dose therapy followed by autologous hematopoietic stem cell transplantation has become accepted therapy for patients with relapsed diffuse large B-cell lymphoma. Approximately 20 to 50% of these patients attain long-term disease-free survival, depending on their response to conventional salvage chemotherapy. Lenalidomide and ibrutinib seem to particularly benefit patients with activated B-cell (ABC) subtype. Other agents used as second- or third-line treatments include polatuzumab-vedotin plus bendamustine or rituximab or tafasitamab plus lenalidomide.[19,20] Autologous CD-19–directed, CAR T-cell therapy is now FDA approved for relapsed or refractory disease, especially with high-risk features.[21,A12]

Subtypes of Diffuse Large B-Cell Lymphoma

Approximately 30% of diffuse large B-cell lymphomas originate in extranodal sites. Presentation in certain extranodal sites is associated with unique clinical behaviors that may necessitate diagnostic studies or additional therapy beyond what is used for patients with nodal presentations.

Primary Mediastinal Large B-cell Lymphomas

Primary mediastinal large B-cell lymphomas originate in the thymus and are most common in young women. This subtype shares genetic features with classic Hodgkin lymphoma. This entity is distinguished by the presence of a mediastinal mass, which usually causes symptoms of cough, chest pain, or superior vena cava syndrome. A very large mass (>10 cm) or the existence of a malignant pleural effusion is associated with a worse prognosis.

TREATMENT AND PROGNOSIS

Mediastinal large B-cell lymphoma is treated with the same chemotherapy regimens used for diffuse large B-cell lymphoma, followed, in some cases, by consolidative radiation therapy.[22] R-EPOCH is more likely than R-CHOP (see Table 171-10) to achieve a durable remission without the need for radiotherapy. Relapses often occur in extranodal sites such as the CNS, lungs, gastrointestinal tract, liver, ovaries, and kidneys.

Intravascular Large B-cell Lymphoma

Intravascular large B-cell lymphoma is an aggressive lymphoma caused by cells that infiltrate the lumens of small blood vessels. Widespread extranodal involvement is common. Focal neurologic deficits and mental status changes are frequent. Cases are often diagnosed at autopsy, although durable responses to combination chemotherapy have been described.

Primary Effusion Lymphoma

Primary effusion lymphoma is associated with HHV-8 (Chapter 359) and is seen in HIV-infected and other immunosuppressed patients.[23] Effusions occur in serous body cavities. Peripheral lymphadenopathy is not seen. Prognosis is poor despite chemotherapy.

Primary CNS Lymphoma

Primary CNS lymphoma (Chapter 175) is increasing in incidence. Patients with primary CNS lymphoma (Chapter 175) commonly have ocular involvement, and all patients with this diagnosis should have a slit lamp examination.

TREATMENT AND PROGNOSIS

Surgical resection usually is not performed for primary CNS lymphoma, and the primary role of surgery is for diagnosis. Primary lymphomas of the CNS are very sensitive to corticosteroids, but some patients can be cured with chemotherapy regimens incorporating high-dose methotrexate (alone or in combination with other agents such as cytarabine, temozolomide, and rituximab) with or without autologous bone marrow transplant.[24] For primary CNS lymphoma, whole-brain radiotherapy is not as good as chemotherapy,[A13] does not add to the benefit achieved by chemotherapy alone, and is associated with increased neurologic toxicity.

Plasmablastic Lymphoma

Plasmablastic lymphoma is most often seen in patients with HIV infection and frequently presents with involvement of the head and neck. This tumor does not express CD20 and thus does not benefit from treatment with rituximab.

Primary Cutaneous Diffuse Large B-cell Lymphoma

Primary cutaneous diffuse large B-cell lymphoma of the leg (leg type) is one of two presentations of B-cell lymphoma in the skin.[25] This tumor occurs mostly in older patients and follows an aggressive course. This neoplasm must be distinguished from primary cutaneous follicle center lymphoma, which might also be diagnosed as a cutaneous diffuse large B-cell lymphoma but follows an indolent course and requires only local therapy.

Double-Hit, Triple-Hit, and Gray-Zone Lymphomas

Double-hit, triple-hit, and gray-zone lymphomas have rearrangements of *MYC* in combination with *BCL2* and/or *BCL6*. These tumors are now incorporated into an entity called high-grade B-cell lymphoma with rearrangements of *MYC* and *BCL2* and/or *BCL6*. Gray-zone lymphomas may have features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma or features intermediate between mediastinal diffuse large B-cell lymphoma and classic Hodgkin lymphoma.

TREATMENT AND PROGNOSIS

These lymphomas have a poor outcome when treated with standard chemotherapy regimens. More aggressive regimens such as DA-R-EPOCH (dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin) may improve the outcome of the double- or triple-hit lymphomas.

Testicular, Gastric, and Intestinal Large B-Cell Lymphomas

Large B-cell lymphoma occasionally originates in the testis or gastrointestinal tract.

TREATMENT AND PROGNOSIS

Treatment of primary testicular lymphoma, the most common testicular cancer in men older than age 60 years (Chapter 185), usually consists of orchiectomy followed by combination chemotherapy. Relapse in the contralateral testicle is common, and radiation is usually given to the entire scrotal bed. CNS involvement is common, and prophylactic intrathecal chemotherapy is usually recommended. Late relapses occur frequently.

Diffuse large B-cell lymphoma of the stomach and gastrointestinal tract is treated differently from gastric MALT lymphoma, even if patients have is a history of prior MALT lymphoma. Patients can be cured with surgery and adjunctive radiation or chemotherapy, although surgery is rarely performed for gastric lymphomas because of the morbidity associated with gastric resection. Patients should be treated with chemotherapy regimens used for other diffuse large B-cell lymphomas. Radiation therapy is sometimes used after chemotherapy, although the role of combined-modality treatment is not defined.

BURKITT LYMPHOMA

Burkitt lymphoma is a highly aggressive B-cell lymphoma that is more common in children and immunosuppressed individuals than in healthy adults (see later).[26] Widespread extranodal involvement is common. The endemic form of Burkitt lymphoma is seen most frequently in children who reside in equatorial Africa. Involvement of bones of the jaw is common in this form. The sporadic form of Burkitt lymphoma is seen most commonly in children in the United States. Males are more frequently affected. Both children and adults frequently have bulky abdominal disease, sometimes with involvement of the kidneys, ovaries, and breasts. Bone marrow involvement is seen in about one third of cases.

TREATMENT

Tumors may progress extremely rapidly, so therapy should be started as soon as possible. Tumor lysis syndrome (Chapter 164) may occur because of the frequent presence of bulky disease, the high rate of tumor proliferation, and the extreme sensitivity of the tumor to chemotherapy. Patients are usually treated with specialized high-intensity regimens, including rituximab, of relatively short duration.[A14] Treatment with the R-CHOP regimen used for diffuse large B-cell lymphoma has a poor outcome, but excellent results have been described with R-EPOCH. CNS prophylaxis with intrathecal chemotherapy or high-dose methotrexate is required. Cure rates well in excess of 50% are typical with appropriate therapy.[27]

RARE TYPES OF B-CELL LYMPHOMA

Several rare types of lymphoma have distinct clinical features.

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma is an indolent lymphoma that frequently involves the bone marrow, peripheral blood, and spleen. Patients frequently have an immunoglobulin M (IgM) paraprotein that may lead to symptoms of hyperviscosity, autoimmune phenomena, or neuropathies. Plasmapheresis can reduce symptoms of hyperviscosity.

TREATMENT AND PROGNOSIS

Chemotherapy with alkylating agents, combination chemotherapy, or fludarabine all in combination with rituximab may be used. Ibrutinib and other Bruton tyrosine kinase (BTK) inhibitors have shown significant activity in lymphoplasmacytic lymphoma, and the combination of ibrutinib plus rituximab has resulted in significantly higher rates of progression-free survival than rituximab alone.[A15]

Splenic Marginal Zone Lymphoma

Splenic marginal zone lymphoma is an indolent lymphoma that usually manifests with splenomegaly and lymphocytosis. A monoclonal gammopathy is frequently seen. Peripheral lymphadenopathy is unusual. Anemia and thrombocytopenia may respond to splenectomy.

TREATMENT AND PROGNOSIS

Chemotherapy with single agents or anthracycline-based combinations may be useful, and when the lymphoma is associated with hepatitis C, antiviral therapy may be effective (Chapter 134 and 135). This lymphoma appears to be particularly responsive to rituximab with or without bendamustine. Bruton kinase inhibitors are also very useful for marginal zone lymphoma treatment.[28]

Nodal Marginal Zone B-cell Lymphoma

Nodal marginal zone B-cell lymphoma is an indolent disorder that is usually associated with generalized lymphadenopathy. The clinical course and prognosis are similar to those of follicular lymphoma, and it is usually treated in a similar manner.

Small Intestinal Immunoproliferative Disease

Small intestinal immunoproliferative disease, which is a disorder seen most frequently in the Middle East, begins as a polyclonal process and can progress to a large B-cell lymphoma. The process is often associated with *C. jejuni* infection (Chapter 279). Early in the disease, patients may respond to antibiotics, and frank lymphoma may respond to combination chemotherapy regimens.

MATURE T-CELL LYMPHOMAS (PERIPHERAL T-CELL LYMPHOMAS)

Peripheral (or mature) T-cell lymphomas are neoplasms of post-thymic T cells. These include relatively indolent disorders such as mycosis fungoides and $CD30^+$ cutaneous lymphoproliferative disorders, but most patients diagnosed with peripheral T-cell lymphoma have an aggressive neoplasm.[29] Peripheral T-cell lymphomas represent only 10% of the non-Hodgkin lymphomas occurring in the United States. Unfortunately, the treatment for these lymphomas has not progressed as rapidly as the treatments for B-cell lymphomas.

MYCOSIS FUNGOIDES

Mycosis fungoides (often referred to as *cutaneous T-cell lymphoma*) is an indolent malignancy that is most common in middle-aged and older adults.[30] The clinical course is usually a slow progression from isolated patches or plaques to thickened, more widespread plaques and then to multiple cutaneous tumors that may ulcerate (Chapter 407). A subset of patients presents with generalized erythroderma and circulating tumor cells, called *Sézary syndrome*. Lymph node and visceral involvement may occur late in the course of the disease.

TREATMENT

Cutaneous radiation therapy may be curative for patients with limited patch or plaque disease. Patients with early-stage disease (<10% body surface area) are frequently treated with skin-directed therapy that may include ultraviolet radiation, topical steroids, or topical nitrogen mustard.

Patients with more advanced disease frequently benefit from total skin electron beam therapy or extracorporeal photopheresis. Medical treatments include brentuximab vedotin, with[A16] or without[A17] standard chemotherapy, bexarotene (a selective retinoid X receptor agonist), interferon-α, retinoids, monoclonal antibodies, histone deacetylase inhibitors (vorinostat, romidepsin), and mogamulizumab (a monoclonal antibody directed against C-C chemokine receptor 4).[A18]

Unfortunately, treatments are usually only palliative.[31] Results with autologous hematopoietic stem cell transplantation are usually poor, although allogeneic stem cell transplantation has yielded promising results in some selected young patients.

ADULT T-CELL LYMPHOMA/LEUKEMIA

Adult T-cell lymphoma/leukemia, which is associated with HTLV-1 infection (Chapter 360), is most commonly seen in southern Japan and the Caribbean. Most infected patients are asymptomatic, and the lifetime risk for developing adult T-cell lymphoma/leukemia is approximately 3%.

Patients may have acute leukemia, aggressive lymphoma, or an indolent lymphoproliferative disease. Patients with aggressive disease present with generalized lymphadenopathy, hepatosplenomegaly, cutaneous infiltration, and hypercalcemia. Many patients have characteristic circulating tumor cells with a "flower" or "cloverleaf" nucleus.

TREATMENT

Patients with indolent disease can sometimes be monitored without therapy. Aggressive disease is usually treated with combination chemotherapy, but there is no consensus on the best regimen. Historically, the 5-year survival rate has been less than 10%, although recent trials have reported better outcomes.

$CD30^+$ CUTANEOUS LYMPHOPROLIFERATIVE DISORDERS

These disorders represent a spectrum of diseases that may have an identical histologic appearance and overlapping clinical manifestations. Treatment decisions are often based on the clinical behavior of the lesions. These lymphomas express CD30 but do not express the anaplastic lymphoma kinase (ALK) protein (see later).

Lymphomatoid Papulosis

Lymphomatoid papulosis is a "histologically malignant" clonal disorder consisting of erythematous or skin-colored papules that frequently undergo spontaneous ulceration and necrosis over a period of weeks. The prognosis is excellent, although patients may eventually develop lymphoma.

Primary Cutaneous Anaplastic Large Cell Lymphoma

Primary cutaneous anaplastic large cell lymphoma occurs most commonly in men and undergoes frequent spontaneous regression. The 5-year survival rate is greater than 90%. Treatment usually consists of local measures (surgery or radiation), although chemotherapy may be required.

PRIMARY SYSTEMIC ANAPLASTIC LARGE CELL LYMPHOMA

Anaplastic large cell lymphoma is an aggressive CD30$^+$ T-cell non-Hodgkin lymphoma that is seen most frequently in young males.[32] B-cell lymphomas with similar morphology can occur, but they have clinical features identical to other diffuse large B-cell lymphomas and are not considered part of this disease. A morphologically similar but biologically unrelated and clinically distinct neoplasm, primary cutaneous anaplastic large cell lymphoma, occurs predominantly in older adults and represents part of the spectrum of cutaneous CD30$^+$ lymphoproliferative disorders (see earlier). Primary systemic anaplastic large cell lymphoma frequently has a t(2;5) chromosomal translocation that leads to overexpression of ALK, a protein not normally detectable in lymphoid cells.

Patients usually have lymphadenopathy, and involvement of the skin, bone, and gastrointestinal tract may be observed.

A newly described entity of anaplastic large cell lymphoma of the breast is associated with breast implants. When localized, patients may be cured with surgery, including removal of the implant.

TREATMENT

Patients are usually treated with chemotherapy regimens such as CHOP with or without the addition of etoposide. Patients whose tumors express ALK have an excellent outcome, and 5-year survival rates of 70 to 90% have been observed. ALK-negative anaplastic large cell lymphoma is more common in older patients and is associated with an inferior response rate and shorter survival time. Autologous hematopoietic stem cell transplantation may be curative for patients who relapse. The anti-CD30 antibody-drug conjugate brentuximab vedotin is highly active for patients with relapsed disease and may be incorporated into primary therapy.[A19] Patients whose lymphomas express ALK usually respond to the ALK inhibitor crizotinib.

Anaplastic large cell lymphoma of the breast extends beyond the breast capsule. It is treated similarly to advanced-stage anaplastic large cell lymphoma.

PERIPHERAL T-CELL LYMPHOMAS, UNSPECIFIED

The largest group of patients with peripheral T-cell lymphomas is defined in the WHO classification as having "peripheral T-cell lymphoma, unspecified." These patients' signs and symptoms are similar to those of patients with aggressive B-cell lymphomas, although systemic symptoms (fevers, night sweats, and weight loss) and extranodal involvement are frequent. The diagnosis of peripheral T-cell lymphoma requires immunophenotyping to demonstrate the T-cell origin.

TREATMENT

Patients are generally treated with the same regimens used for diffuse large B-cell lymphomas (e.g., CHOP with or without etoposide), often in combination with upfront autologous hematopoietic stem cell transplantation, although the outcome is substantially worse. Belinostat is a histone deacetylase inhibitor that has some activity in peripheral T-cell lymphoma.[33] Patients who relapse after complete remission can sometimes be cured with hematopoietic stem cell transplantation.

UNUSUAL SUBTYPES OF T-CELL LYMPHOMA

Angioimmunoblastic T-cell Lymphoma

Angioimmunoblastic T-cell lymphoma is associated with generalized lymphadenopathy, fever, weight loss, skin rash, and polyclonal hypergammaglobulinemia. Results of therapy are similar to those for peripheral T-cell lymphoma, unspecified.

Extranodal NK/T-cell Lymphoma

Extranodal NK/T-cell lymphoma usually occurs in extranodal sites, especially the nose, palate, and nasopharynx. Involvement of the nose and face leads to the syndrome that was previously called lethal midline granuloma. This disorder is unusual in the United States, but it is frequent in Southeast Asia and Latin America. Patients with localized disease often can be cured with aggressive combination radiation therapy and chemotherapy.[34] Patients with widespread disease have a poor prognosis. These patients frequently respond to L-asparaginase.

Hepatosplenic T-cell Lymphoma

Hepatosplenic T-cell lymphoma is characterized by sinusoidal infiltration of the spleen, liver, and bone marrow, which leads to hepatosplenomegaly, systemic symptoms, and cytopenias. Lymphadenopathy is unusual. Hepatosplenic T-cell lymphoma is more commonly occurs in young men, and this disease can occur in the setting of immune dysfunction. The prognosis is poor.

Enteropathy-type T-cell Lymphoma

Enteropathy-type T-cell lymphoma is usually seen in patients with gluten-sensitive enteropathy (Chapter 126). Patients typically present with abdominal pain and diarrhea and sometimes with bowel perforation. Treatment of celiac disease with a gluten-free diet may reduce the risk for lymphoma. The prognosis in undernourished patients is poor, but more fit patients can sometimes be cured with intensive chemotherapy and autologous bone marrow transplant.

Subcutaneous Panniculitis-like T-cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma manifests with multiple subcutaneous nodules and is often misdiagnosed as panniculitis. Patients with disseminated disease can have a syndrome consisting of fevers, weight loss, hepatosplenomegaly, pancytopenia, and phagocytosis of blood cells (hemophagocytic syndrome). Patients sometimes respond to combination chemotherapy regimens used for diffuse large B-cell lymphoma, interferon, and radiation therapy, but long-term disease-free survival is unusual.

SPECIAL CLINICAL SITUATIONS

The diagnosis and management of patients with the various types of non-Hodgkin lymphoma can be profoundly influenced by the site of origin of the lymphoma and by certain clinical characteristics of the individuals affected with the disease. Examples of the latter include lymphoma in patients who are severely immunosuppressed because of HIV infection or a prior transplant, elderly patients with lymphoma, and pregnant patients with lymphoma.

LYMPHOMA IN AIDS

Non-Hodgkin lymphoma is an AIDS-defining illness in HIV-infected individuals (Chapters 355 and 359), and the risk for developing a non-Hodgkin lymphoma is increased more than 150-fold after the diagnosis of another AIDS-defining illness.[35] Most cases are diffuse large B-cell lymphomas or Burkitt lymphomas. AIDS-associated lymphomas behave aggressively and frequently involve the CNS and other unusual sites, such as the gastrointestinal tract, anus, rectum, skin, and soft tissue. Factors associated with poor survival include low CD4 counts, poor performance status, older age, and advanced stage. The incidence of AIDS-associated non-Hodgkin lymphoma has declined, and the prognosis has improved considerably.

TREATMENT

Patients are generally treated in the same manner as nonimmunocompromised patients, and the prognoses are similar. Intrathecal prophylaxis is generally recommended because of a higher risk for CNS involvement.

POST-TRANSPLANT LYMPHOPROLIFERATIVE DISEASE

The risk for developing a non-Hodgkin lymphoma is also markedly increased in patients who have received a solid organ transplant. The histologic appearance of these lymphomas is variable, but they frequently resemble aggressive lymphomas in nonimmunocompromised patients. Epstein-Barr virus (Chapter 348) is almost always the causative agent. Similar disorders can be seen in patients who are treated with methotrexate and other drugs for autoimmune disorders and in recipients of allogeneic hematopoietic stem cell transplants, especially if the transplants are T-cell depleted. These post-transplantation lymphoproliferative disorders, which may develop within weeks after surgery, are more common in patients who receive aggressive immunosuppression after transplantation. Involvement of extranodal sites is common, and lymphoma frequently involves the transplanted organ.

TREATMENT

Post-transplantation lymphoproliferative disorders may respond to reduction or withdrawal of immunosuppression.[36] Acyclovir or ganciclovir can be considered, because these lymphomas are usually related to Epstein-Barr virus, but this practice is controversial. High response rates are also seen with rituximab. Other patients require treatment with combination chemotherapy regimens including rituximab.

NON-HODGKIN LYMPHOMA IN ELDERLY PATIENTS

More than 50% of patients who develop non-Hodgkin lymphomas are older than age 60 years, and the prognosis is generally worse for elderly patients. These poorer outcomes are related to increased toxicity of drug therapy, lower remission rates, increased rates of relapse, and higher death rates from cardiovascular disease and causes other than the lymphoma itself. Older patients are more likely to have other adverse prognostic characteristics (see Table 171-8), which also contribute to poorer outcomes. The practice of arbitrary dose reductions based solely on age should be discouraged if patients have a good performance status and no comorbid illnesses.

NON-HODGKIN LYMPHOMA AND PREGNANCY

Non-Hodgkin lymphoma in pregnancy involves major clinical and ethical issues, and a multidisciplinary approach is needed. Although chest radiographs are generally considered safe, ultrasound examination is usually used instead of CT for staging in the abdomen and pelvis.

TREATMENT

Treatment occasionally can be delayed until after delivery. However, most women have a lymphoma that is potentially curable, and delays in treatment may decrease the chance for cure. Other patients have conditions such as superior vena cava syndrome that require immediate treatment. After the first trimester, full-dose standard therapy such as R-CHOP may be used. Several studies indicate high probabilities of cure without significantly increased adverse long-term physical or intellectual deficits for the child. Although it is reasonable to offer therapeutic abortion for women in the first trimester, chemotherapy also may be successful in this situation. Regimens using methotrexate or abdominal radiation must be avoided.

DISEASES SOMETIMES CONFUSED WITH LYMPHOMA

A variety of conditions are associated with lymphadenopathy that can be confused with lymphoma. The most common atypical lymphoid proliferations that can be confused with lymphoma are florid reactions to immune stimulation. Follicular hyperplasia with diffuse proliferation of B cells and T cells can be seen in a variety of autoimmune diseases (e.g., Sjögren syndrome [Chapter 247], systemic lupus erythematosus [Chapter 245], rheumatoid arthritis [Chapter 243]) and infectious processes (e.g., Epstein-Barr virus [Chapter 348], cytomegalovirus [Chapter 247], cat-scratch disease [Chapter 291]). If the definitive diagnosis of lymphoma cannot be made even after immunologic and molecular studies, the patient should be closely observed. The clinical course or subsequent biopsies can usually resolve the confusion.

Castleman Disease

Castleman disease, or angiofollicular lymph node hyperplasia, usually appears with a hyaline vascular pattern of lymphoid proliferation, but a subset of patients has hyperplastic lymphoid follicles and sheets of plasma cells.[37] Patients with Castleman disease often present with a localized lymphoid mass, but some patients have a systemic illness with fevers, night sweats, weight loss, and fatigue. Frequently, the systemic symptoms of Castleman disease are related to excessive production of IL-6. Castleman disease in HIV-infected patients is frequently associated with HHV-8 (Chapter 358).

TREATMENT

Patients with disseminated and plasma cell–rich forms of Castleman disease may occasionally progress to lymphoma. Patients with localized Castleman disease can be treated with surgical removal, radiation therapy, or occasionally observation if asymptomatic.[38] Patients with systemic disease may respond to treatment with high-dose corticosteroids and/or rituximab. Patients with overexpression of IL-6 frequently benefit from treatment with an anti–IL-6 antibody. For example, siltuximab (a chimeric monoclonal antibody against interleukin 6 at 11 mg/kg intravenous infusion every 3 weeks) can provide durable responses in about one third of HIV-negative patients.[39] If other treatments fail, patients sometimes benefit from combination chemotherapy regimens, autologous or allogeneic hematopoietic stem cell transplantation, or both.[40] The mammalian target of rapamycin (mTOR) inhibitor sirolimus also is a potentially promising agent.

Sinus Histiocytosis with Massive Lymphadenopathy

Sinus histiocytosis with massive lymphadenopathy, also known as Rosai-Dorfman disease (Chapter 154), manifests as bulky lymphadenopathy in children and young adults. Extranodal sites such as the skin, upper airways, gastrointestinal tract, and CNS can be involved. The disease is usually self-limited, but it has been associated with autoimmune hemolytic anemia.

Kikuchi Disease (Histiocytic Necrotizing Lymphadenitis)

Kikuchi disease (histiocytic necrotizing lymphadenitis) is a disease of unknown origin that most commonly affects young women. Symptoms most commonly consist of painless cervical lymphadenopathy that is often accompanied by fever, flulike symptoms, and rash. Treatment is symptomatic, and manifestations usually resolve within weeks or months.

IgG4-related Disease

IgG4-related disease is a systemic immune-mediated fibrosing inflammatory disease in which various organs are infiltrated by IgG4-positive plasma cells (Chapter 254). Patients often have accompanying asymptomatic lymphadenopathy that usually responds to corticosteroids.

172 HODGKIN LYMPHOMA

JOSEPH M. CONNORS AND KERRY J. SAVAGE

DEFINITION

Hodgkin lymphoma, one of the B-cell lymphomas, consists of two major types: classic Hodgkin lymphoma, with a characteristic neoplastic cell, the Hodgkin-Reed-Sternberg cell; and the much less common (~10% of cases) nodular lymphocyte-predominant Hodgkin lymphoma, with a characteristic predominance of small lymphocytes. Both types have a distinct natural history, and most important, an excellent response to treatment, with the large majority of patients being cured. Highly effective multiagent chemotherapy is the cornerstone of treatment. Carefully selected patients may require the addition of radiation or, if the lymphoma recurs after primary treatment, high-dose chemoradiation therapy and autologous hematopoietic cell transplantation. The major challenge to clinicians managing this neoplasm is to cure the disease while minimizing long-term toxicity.

EPIDEMIOLOGY

The incidence of Hodgkin lymphoma varies substantially around the world. The highest rates occur in the United States, Canada, Switzerland, and northern Europe. Intermediate rates are seen in southern and eastern Europe and low rates in eastern Asia. No clear explanation for this variation has been found. Postulated reasons include differences in the age at onset or genotype of an associated Epstein-Barr virus infection; crowding during childhood as a result of lower socioeconomic status, predisposing to passage of an as-yet-undiscovered infectious vector; and intrinsic genetic differences in susceptibility.

Approximately 30,000 new cases are diagnosed annually in North America and Europe. The age-adjusted incidence of Hodgkin lymphoma declined modestly over the 20 years before 1990 but has leveled off since then at approximately 2.7 per 100,000. Age-adjusted annual mortality is 0.5 per 100,000. Hodgkin lymphoma occurs slightly more often in men and is seen more frequently in Whites than Blacks and much less frequently in Asian populations. Much of the difference in incidence between Whites and Blacks in North America can be attributed to the higher incidence seen in higher socioeconomic classes. The cumulative lifetime risk for Hodgkin lymphoma is approximately 1 in 250 to 1 in 300 in North America.

The incidence of Hodgkin lymphoma is bimodal in age distribution, rising from very low in childhood to an early peak in young adulthood (25 to 30 years) and a later peak in late adulthood (>50 years). In the Western world, only about 5% of cases occur in persons younger than 15 years of age and 5% in individuals older than 70 years of age. In contrast, the age distribution in the Indian subcontinent is strongly shifted into childhood.

PATHOBIOLOGY

The cause of Hodgkin lymphoma remains unclear. It is not associated with exposure to radiation, chemicals, biocidal agents, working in health care–related professions, or previous tonsillectomy. The leading suspect remains Epstein-Barr virus, based on much suggestive evidence but no definitive proof.[1]

Epstein-Barr Virus

Epstein-Barr virus is a large B-lymphocyte tropic herpesvirus (Chapter 348). Approximately 90% of the general population acquires infection by early adulthood. In the developing world, this infection usually occurs in childhood, but in developed countries, infection is often delayed into the teens, when it is associated with the syndrome of infectious mononucleosis in up to 30% of new cases. A history of infectious mononucleosis increases the likelihood for subsequent Hodgkin lymphoma three-fold. Antibodies to the viral capsid antigen reach higher levels in patients with Hodgkin lymphoma than in controls, and these higher levels appear several years before the neoplasm. In situ hybridization studies have demonstrated that the Hodgkin-Reed-Sternberg cells in approximately 50% of cases of Hodgkin lymphoma contain Epstein-Barr virus-encoded small RNA. In these cases, virtually all the Hodgkin-Reed-Sternberg cells are positive for the virus; the Epstein-Barr virus genome is amplified 50-fold or more in Hodgkin-Reed-Sternberg cells; and is monoclonal in an individual patient's Hodgkin-Reed-Sternberg cells. In some populations, virtually all cases of Hodgkin lymphoma occur in Epstein-Barr virus–positive individuals (<15 or >65 years of age; non-European ancestry; low socioeconomic status), but up to 50% of patients in developed countries do not have Epstein-Barr virus in their Hodgkin-Reed-Sternberg cells. Thus, although Epstein-Barr virus may play an important role in the development of Hodgkin lymphoma, that role is neither straightforward nor universal.

Genetic Factors

Circumstantial evidence for a genetic contribution to the etiology of Hodgkin lymphoma comes from studies showing that Hodgkin lymphoma is almost 100-fold more likely to develop in the monozygotic twin of an affected individual than in a dizygotic twin. First-degree relatives of individuals with the disease have up to a five-fold increased risk for development of the lymphoma. Genome-wide association studies have identified multiple genetic risk variants, which have been detected primarily in immune-related genes. For example, variants in *GATA3*, *IL13*, and genes controlling the expression of HLA class II molecules have been associated with the Epstein-Barr virus–negative nodular sclerosing subtype of classic Hodgkin lymphoma, which is seen predominantly in adolescents and young adults.

Polymerase chain reaction–based genotypic analysis has demonstrated the clonal derivation of Hodgkin-Reed-Sternberg cells, including identical *p53* mutations from multiple Hodgkin-Reed-Sternberg cells extracted from a single biopsy specimen, thereby unequivocally establishing clonality. The presence of clonal immunoglobulin gene rearrangements from multiple cells in the same biopsy specimen also confirms a B-cell origin.[2] Only a few rare cases with a T-cell genotype have been reported. Finally, identification of cells with identical immunoglobulin gene rearrangements, both at diagnosis and at relapse, verify that the B-cell clonality of the disease is preserved over time.

Aneuploidy and hyperploidy consistent with the multinucleated nature of Hodgkin-Reed-Sternberg cells are frequent, but no consistent chromosomal translocations have been detected. Several susceptibility loci for Hodgkin lymphoma have been localized to active chromatin with an overrepresentation of determinants of B-cell development and immune response.

Despite their B-cell origin, the neoplastic cells of Hodgkin lymphoma are incapable of making intact antibodies, perhaps because they lack the ability to make the transcription factors necessary to activate the immunoglobulin promoter. B cells that are incapable of manufacturing antibody should undergo apoptosis and immune destruction, but the Hodgkin-Reed-Sternberg cells avoid cell death by activating NFκB and thereby impeding apoptosis and inducing immune blockade by overexpressing checkpoint inhibitors such as programmed cell death ligands 1 and 2.

CLINICAL MANIFESTATIONS

Hodgkin lymphoma is usually manifested as lymphadenopathy (Chapter 154), typically in the cervical, axillary, or mediastinal areas for the predominant classic Hodgkin lymphoma, and only about 10% of patients present with nodal disease below the diaphragm. Although peripherally located nodes seldom reach large size, very large mediastinal masses or, less often, retroperitoneal masses can develop with only modest symptoms. Lymph node involvement in Hodgkin lymphoma is usually painless, but an occasional patient notes discomfort in involved nodal sites immediately after drinking alcohol.

Approximately 25% of patients with Hodgkin lymphoma have constitutional symptoms. The classic B symptoms—significant weight loss (>10% of baseline), night sweats, and persistent fever—usually signal widespread or locally extensive disease and imply a need for systemic treatment. Generalized pruritus, occasionally severe, can antedate the diagnosis of Hodgkin lymphoma by up to several years. Some patients have symptoms suggestive of a growing mass lesion, such as cough or stridor as a result of tracheobronchial compression from mediastinal disease or bone pain secondary to metastatic involvement. Because Hodgkin lymphoma can rarely involve the bone marrow extensively, an occasional patient presents with symptomatic anemia or incidentally noted pancytopenia. Paraneoplastic neurologic or endocrine syndromes (Chapter 164) have been reported with Hodgkin lymphoma but are rare.

DIAGNOSIS

The diagnosis of classic Hodgkin lymphoma is based on recognition of Hodgkin-Reed-Sternberg cells (Fig. 172-1) or Hodgkin cells (or both) in an appropriate cellular background in tissue sections from a lymph node or extralymphatic organ, such as bone marrow, lung, or bone. Fine-needle aspiration biopsy is not adequate for the diagnosis of Hodgkin lymphoma. Open biopsy and standard histochemical staining are required to establish the diagnosis unequivocally and to determine the histologic subtype.[3]

ABSTRACT

Approximately 30,000 new cases of Hodgkin lymphoma, an uncommon but frequently curable B-cell lymphoma, are diagnosed annually in North America and Europe. The etiology of Hodgkin lymphoma remains unknown, and it occurs with biphasic incidence peaking in adults in their mid-30s and again in those over the age of 50 years. Multiagent chemotherapy, occasionally complemented by therapeutic involved-field radiation, is the cornerstone of treatment and cures most patients. The 30% of patients with limited extent of disease require only brief chemotherapy, typically over 3 to 4 months; those with more extensive disease need more extended chemotherapy for 6 months. In both groups, functional imaging with fluorodeoxyglucose positron emission tomography helpfully separates the majority of patients who have had a complete remission from the minority with possible persistent localized lymphoma that may still be cured with the addition of radiation. If, despite optimal primary treatment, the lymphoma recurs, high-dose chemoradiation followed by autologous hematopoietic cell transplantation can cure approximately 50% of patients. Novel treatments with antibody-drug conjugates targeting unique cell surface characteristics on the malignant cells and immune checkpoint inhibitors that neutralize immune response-paralyzing factors produced by the malignant cells are highly effective for Hodgkin lymphoma and are undergoing clinical trials integrating their use into standard management. With most patients cured using current treatments, the major challenge to clinicians managing this neoplasm today is for the cure to be achieved while minimizing long-term toxicity.

Hodgkin lymphoma can typically be classified into well-described subtypes (Table 172-1), including a relatively new category of lymphocyte-rich classic Hodgkin lymphoma, which must be distinguished from nodular lymphocyte-predominant Hodgkin lymphoma. The most common subtype is nodular sclerosing, which has characteristic coarse bands of sclerosis surrounding nodules composed of typical Hodgkin-Reed-Sternberg cells in the usual background mixture of reactive and inflammatory cells.

In classic Hodgkin lymphoma, scattered large Hodgkin-Reed-Sternberg cells either are multinucleated or have large polyploid nuclei. Variations include mononuclear cells that are similar to the usual polylobated or multinuclear cells but have only one large nucleus with a prominent nucleolus, as well as lacunar cells, which are Hodgkin-Reed-Sternberg variants with abundant cytoplasm that has retracted as an artifact of formalin fixation. The infrequent Hodgkin-Reed-Sternberg cells are usually present in a background mixture of polyclonal lymphocytes, eosinophils, neutrophils, plasma cells, fibroblasts, and histiocytes. A high number of associated macrophages has been demonstrated to be a strong predictor of treatment resistance. Occasionally, granulomas form with a prominent histiocytic component. In contrast, in nodular lymphocyte-predominant Hodgkin lymphoma the cellular pattern predominantly consists of small lymphocytes and scattered histiocytes, epithelioid histiocytes, and characteristic large neoplastic lymphocytic cells ringed by non-neoplastic T lymphocytes.

The immunophenotype of the neoplastic cells in Hodgkin lymphoma can help identify the specific subtype. Typically, the Hodgkin-Reed-Sternberg cells stain positively for CD30 (90 to 100% of cases), CD15 (75 to 85% of cases), and B-cell-specific activating protein (BSAP), which is the product of the *PAX5* gene (>90% of cases). CD20, a generally reliable marker of B-cell lineage, is positive in about 40% of cases of classic Hodgkin lymphoma, but usually only in a minority of cells, and the staining can be weak. In contrast, nodular lymphocyte-predominant Hodgkin lymphoma almost always stains strongly positive for CD20 and for the specialized B-cell markers CD79a and CD45 but is negative for CD30 and CD15. Anaplastic large cell lymphoma (Chapter 171) is positive for CD30 but reliably negative for CD15, CD20, and CD79a.

SUBTYPE NAME	FREQUENCY (%)*
Classic Hodgkin lymphoma	
Nodular sclerosing	60
Lymphocyte rich	3
Mixed cellularity	9
Lymphocyte depleted	1
Nodular lymphocyte-predominant Hodgkin lymphoma	8
Hodgkin lymphoma, not otherwise classifiable	19

*Frequency based on all new cases (N = 2488) seen in British Columbia from January 1998, when the category of lymphocyte-rich classic Hodgkin lymphoma became well established, to December 2020.

Differential Diagnosis

Depending on the site of occurrence and associated symptoms, the differential diagnosis of Hodgkin lymphoma includes non-Hodgkin lymphoma (Chapter 171), primary mediastinal B cell lymphoma, mediastinal gray zone lymphoma, germ cell tumors (Chapters 184 and 185), thymoma (Chapter 390), sarcoidosis (Chapter 83), histiocytosis (Chapter 155), and tuberculosis (Chapter 299). However, the specific diagnosis is readily determined by obtaining an adequate biopsy specimen for review by an experienced hematopathologist. T-cell/histiocyte–rich B-cell lymphoma (Chapter 171) is distinguished from nodular lymphocyte-predominant Hodgkin lymphoma, which it otherwise closely resembles, by being CD30 negative but positive for IgD mantle cells and follicular dendritic cell networks. Proceeding to a biopsy early in the assessment of patients with lymphadenopathy (Chapter 154), especially of the mediastinum, often saves time and avoids delay in diagnosis. With appropriate biopsy procedures to investigate enlarged central thoracic or intra-abdominal lymph nodes, the diagnosis of Hodgkin lymphoma seldom presents difficulty. The immunophenotype helps distinguish Hodgkin lymphoma from other diseases. The combination of appropriate immunohistopathologic evaluation by an expert hematopathologist and clinical assessment has virtually eliminated difficulties with the differential diagnosis. Problems mostly arise when inadequate or improperly processed material is all that is available for diagnosis.

Staging

Physical Examination

The stage of Hodgkin lymphoma can be established by using readily available imaging and laboratory tests (Fig. 172-2 and Table 172-2). The evaluation should start with a careful history to search for the presence of localizing signs, such as bone pain, or the constitutional symptoms of fever, weight loss, or night sweats or comorbid conditions that may affect the safe delivery of planned treatment. The physical examination may identify lymphadenopathy or organomegaly.

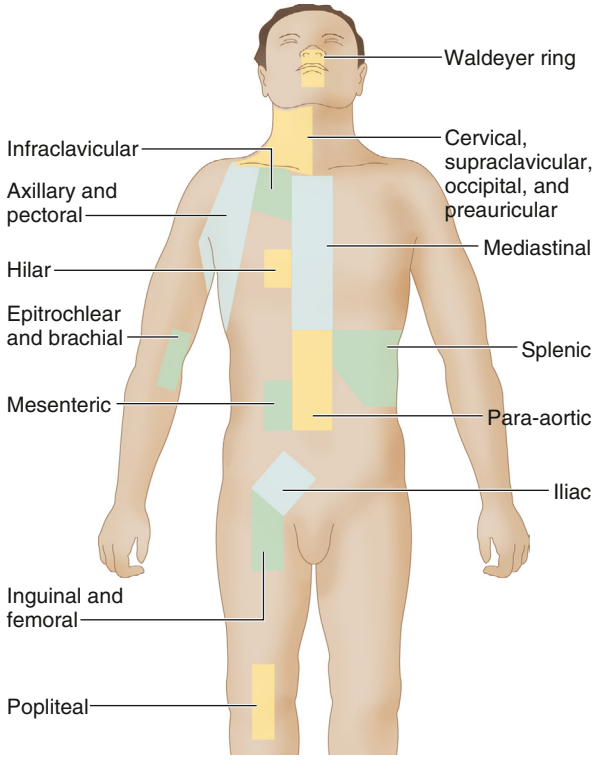

FIGURE 172-2. Anatomic definition of lymph node regions for staging of Hodgkin disease. (From Kaplan HS, Rosenberg SA. The treatment of Hodgkin disease. *Med Clin North Am*. 1966;50:1591-1610.)

TABLE 172-2 TESTS REQUIRED FOR STAGING OF HODGKIN LYMPHOMA

Complete history to search for B symptoms (fever, weight loss, night sweats) or other symptomatic problems suggesting more advanced disease
Physical examination for lymphadenopathy or organomegaly
Complete blood count
Serum creatinine, alkaline phosphatase, lactate dehydrogenase, bilirubin, and protein electrophoresis (including serum albumin level)
Chest radiograph, posteroanterior and lateral views
Computed tomography scan of the neck, thorax, abdomen, and pelvis
Fluorodeoxyglucose positron emission tomography with computed tomography (PET/CT)

TABLE 172-3 MODIFIED ANN ARBOR STAGING SYSTEM FOR HODGKIN LYMPHOMA

STAGE	INVOLVEMENT
I	Single lymph node region (I) or one extralymphatic site (I_E)
II	Two or more lymph node regions, same side of the diaphragm (II), or local extralymphatic extension plus one or more lymph node regions, same side of the diaphragm (II_E)
III	Lymph node regions on both sides of the diaphragm (III); may be accompanied by local extralymphatic extension (III_E)
IV	Diffuse involvement of one or more extralymphatic organs or sites
A	No "B" symptoms
B	Presence of at least one of the following: Unexplained weight loss >10% of baseline during 6 months before staging Recurrent unexplained fever >38° C Recurrent night sweats

Laboratory Testing

Laboratory testing should include blood cell counts and the erythrocyte sedimentation rate, assessment of liver and renal function, serum albumin level, serum protein electrophoresis, and serologic testing for human immunodeficiency virus (HIV) as well as hepatitis B and C. Bone marrow aspiration and biopsy have been rendered unnecessary by fluorodeoxyglucose positron emission tomography (PET).

Imaging

Imaging techniques to evaluate Hodgkin lymphoma continue to evolve (Fig. 172-3). All patients should undergo contrast-enhanced computed tomography (CT) scanning of the neck, thorax, abdomen, and pelvis with slices at intervals of 1 cm or less. Magnetic resonance imaging is occasionally useful when the extent of bone or soft tissue involvement must be determined precisely or for a patient with an absolute contraindication to the use of intravenous contrast agents.

Positron Emission Tomography

Fluorodeoxyglucose PET is more sensitive and specific than CT or gallium scanning both for staging and for assessment of residual masses after treatment, and it is now considered mandatory for staging and following patients with Hodgkin lymphoma.[4-6] For staging, PET imaging reliably detects Hodgkin lymphoma and therefore precludes the need for a bone marrow aspirate or biopsy and is very useful for the assessment of residual masses during or after planned treatment, thereby allowing better selection of patients who should receive altered or additional therapy, especially radiotherapy.

Staging System

The Ann Arbor staging system with the Cotswold modification (Table 172-3) categorizes patients into four stages. The spleen and the lymphoid tissue of the Waldeyer ring each count as nodal sites in this system. Stage IV is reserved for diffuse extranodal disease, which for all practical purposes is disease in the bone marrow, lung, bone, or liver. Hodgkin lymphoma at any other extranodal site should prompt questioning of the diagnosis or a search for HIV infection.

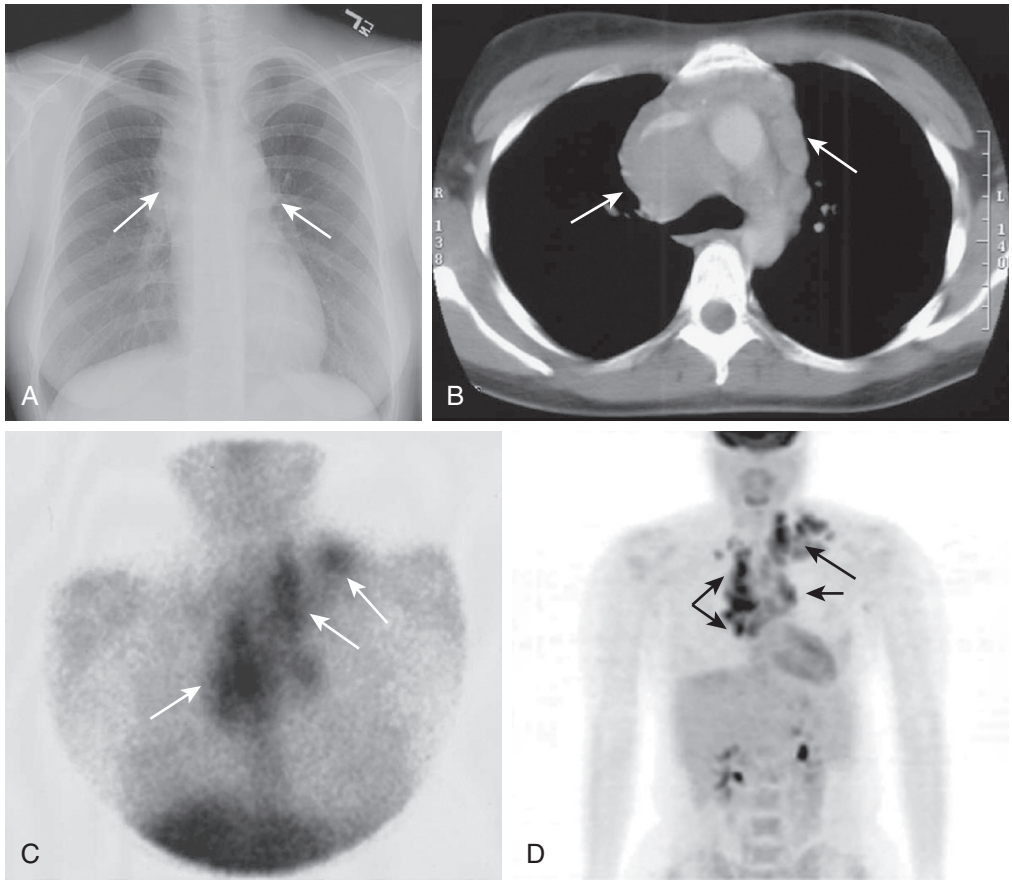

FIGURE 172-3. Imaging of Hodgkin lymphoma. Bulky Hodgkin disease as seen on chest radiograph (**A**), computed tomography (CT) of the chest (**B**), gallium scan (**C**), and positron emission tomography (PET) (**D**). The *arrows* indicate sites of disease. Note that the PET and CT scans provide more detailed information than the chest radiograph and gallium scan.

Bulky disease is defined as the presence of any tumor mass with the largest diameter of 10 cm or more. The E lesion designation identifies patients whose limited extranodal extension of Hodgkin lymphoma could be included in a reasonable involved field of irradiation. As part of staging, patients are further subdivided into those with or without fever, night sweats, or weight loss (B symptoms).

TREATMENT

Hodgkin lymphoma is usually cured.[7] Patients who are event-free at 2 years have an excellent outcome regardless of baseline prognostic factors, although they have an enduring increased risk of death from all causes compared with the general population.[8] Accurate diagnosis, staging, and delivery of appropriate combined-modality treatment and multiagent chemotherapy require a multidisciplinary team, including pathologists, experts in diagnostic imaging, medical and radiation oncologists, nurses, and support staff. The necessity to balance greater efficacy of initial treatment, which often requires an increase in intensity and therefore toxicity, against troublesome and occasionally fatal late complications has encouraged a long-term perspective and careful monitoring for late treatment-related side effects.

Patients with stage III or IV disease or bulky disease are defined as having advanced disease, whereas patients without these characteristics have limited-stage disease. In Europe, patients with limited disease are further subdivided into those with favorable and unfavorable outcomes. Cure rates exceed 90 to 95% for patients with nonbulky stage IA or IIA (limited) disease. However, for patients with advanced-stage disease, independent predictors of progression include sex, age, stage, hemoglobin level, white blood cell count, lymphocyte count, and serum albumin level. Current treatment results indicate a spread from 60 to 80% from the worst to best prognosis groups.[9] A straightforward plan of treatment for the 90% of patients in whom Hodgkin lymphoma is diagnosed between the ages of 16 and 70 years can be based on clinical stage, the presence of B symptoms, and bulk of the largest tumor mass (Table 172-4).

Treatment of Limited-Stage Hodgkin Lymphoma

More than 95% of the one third of patients with Hodgkin lymphoma initially found to have limited-stage disease can be cured regardless of the site of occurrence, the presence of disease above or below the diaphragm, or the histologic subtype. The challenge is to achieve this goal with the least toxicity and cost.[10]

Treatment with two cycles of ABVD (Adriamycin [doxorubicin], bleomycin, vinblastine, and dacarbazine under expert supervision) chemotherapy followed by involved-field or involved site irradiation cures nearly 95% of patients with limited-stage disease; nearly completely eliminates the risk for infertility, premature menopause, and leukemia; and minimizes cardiopulmonary toxicity.[11] However, three cycles of chemotherapy alone is a viable alternative for patients who have limited-stage Hodgkin lymphoma and who have a complete metabolic response, as documented by PET scan, because the reduction in the risks of exposure to radiation offset a slightly higher risk of progressive disease.[A1] For the minority whose lymphoma does not completely regress after three cycles as assessed by PET scanning, the addition of radiation is indicated.

In some European centers, limited-stage Hodgkin lymphoma is divided into favorable (lacking adverse prognostic factors) and unfavorable (bulky mediastinal mass, extranodal extension, elevated erythrocyte sedimentation rate, or involvement of three or more lymph node areas). Patients with limited-stage, favorable Hodgkin lymphoma are treated as described above, but more-intensive approaches have been tested for limited-stage but unfavorable Hodgkin lymphoma with these adverse prognostic factors. In such patients, two cycles of BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) followed by two cycles of ABVD under expert supervision plus involved-field radiotherapy significantly improves tumor control compared with four cycles of ABVD before involved-field radiotherapy, but long-term overall survival is not better.[A2] The addition of a checkpoint inhibitor (e.g., nivolumab or pembrolizumab) either before or concomitantly with four cycles of AVD under expert supervision appears to improve outcome for patients with limited stage, unfavorable Hodgkin lymphoma, in whom it can induce a progression-free survival of >98%,[12,13] but the role for checkpoint inhibitors awaits the results of ongoing clinical trials.

TABLE 172-4 TREATMENT PLAN FOR HODGKIN LYMPHOMA BASED ON STAGE

GROUP	STAGE	TREATMENT
Limited	IA or IIA, no bulky disease*	ABVD† × 2 + IRRT or ABVD × 3 If complete remission, no further treatment If partial remission, add IRRT or a checkpoint inhibitor × 8 doses + AVD × 4
Advanced	IB, IIB, or any stage III or IV or bulky disease, any stage	ABVD† × 6 or A+AVD × 6 or escalated BEACOPP† × 4-6
Refractory/ Relapsed	All stages	Second line chemotherapy followed by high-dose chemoradiation therapy and autologous hematopoietic cell transplantation

*Bulky refers to disease with the largest diameter of any single mass equal to or greater than 10 cm.
†See text for drugs in each regimen. Optimal dosing must be individualized.
A+AVD = brentuximab vedotin, doxorubicin, vinblastine, and dacarbazine; ABVD = Adriamycin [doxorubicin], bleomycin, vinblastine, and dacarbazine; BEACOPP = bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone; IRRT = involved region radiotherapy.

Treatment of Advanced-Stage Hodgkin Lymphoma

Formerly, in advanced-stage Hodgkin lymphoma (stages IIIA, IIIB, IVA, IVB, and in some cases bulky stage II), ABVD for six cycles under expert supervision had been the most widely used regimen.[14] If the PET scan had become negative after two cycles of ABVD, bleomycin could be safely omitted from the remaining four cycles.[A3] More recently, however, the addition of brentuximab vedotin, an anti-CD30 antibody-drug conjugate to doxorubicin, vinblastine, and dacarbazine (A+AVD), has been shown to improve both 5-year progression-free and overall survival compared with ABVD in previously untreated stage III or IV Hodgkin lymphoma and has become standard.[A4,A5] A negative PET scan at the end of chemotherapy distinguishes between residual fibrosis and persistent lymphoma and identifies the 75% of patients with a residual mass who do not require radiation therapy.[A6,A7]

An alternative to ABVD chemotherapy for advanced-stage Hodgkin lymphoma in patients less than 60 years of age is escalated BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone under expert supervision; see Table 172-4), either by itself[15] or used only for patients with a positive interim PET scan after two cycles of ABVD. PET scan results also can guide the intensity of BEACOPP therapy and allow reductions in future doses in patients without detectable residual disease.[A8] Alternatively, BEACOPP may be switched to ABVD if the PET scan is negative after two cycles.[A9,A10] Assessing the appropriateness of escalated BEACOPP for advanced-stage Hodgkin lymphoma requires consideration of potential secondary treatments for those not cured by primary therapy. About 50% of such patients can be effectively treated with high-dose chemoradiation therapy and autologous hematopoietic cell transplantation (Chapter 163). Thus, although escalated BEACOPP offers better initial disease control, randomized trials have failed to demonstrate its superior overall survival compared with ABVD.[A11,A12]

Management of Refractory or Relapsed Hodgkin Lymphoma

For most patients whose Hodgkin lymphoma persists or recurs despite primary chemotherapy, high-dose chemoradiation therapy (e.g., BEAM [carmustine, etoposide, cytarabine, and melphalan] under expert supervision) and autologous hematopoietic cell transplantation is the recommended treatment, if feasible. Approximately one third of patients whose disease progresses during or within 3 months of initial multiagent chemotherapy (refractory Hodgkin lymphoma) and about two thirds of patients who relapse more than 3 months after multiagent chemotherapy (relapsed Hodgkin lymphoma) can be cured using high-dose chemoradiation therapy and autologous hematopoietic cell transplantation.[16] Two special subgroups may be exceptions. Patients who are initially stage I to III but who relapse solely in originally involved but unirradiated lymph nodes and without B symptoms or extranodal disease may obtain up to a 40 to 50% cure rate with wide-field irradiation, and patients who relapse without B symptoms more than 1 year after completion of primary chemotherapy also may achieve up to a 30 to 40% cure rate with additional chemotherapy with or without irradiation. However, these two subgroups may achieve up to an 80% 10-year disease-free survival rate after high-dose chemoradiation therapy and autologous hematopoietic cell transplantation. Thus, data suggest that patients with progressive Hodgkin lymphoma after primary chemotherapy for advanced-stage disease should undergo high-dose chemoradiation therapy and autologous hematopoietic cell transplantation regardless of the characteristics of the relapse. After high-dose chemoradiation therapy and autologous hematopoietic cell transplantation, the addition of consolidative brentuximab vedotin improves outcomes by eliminating approximately one third of the relapses that would have otherwise occurred.[A13,A14] For patients who relapse despite high-dose chemoradiation therapy and autologous hematopoietic cell transplantation, blockade of the programmed death 1 (PD-1) pathway with checkpoint inhibitors (e.g., nivolumab[A15] or pembrolizumab[A16,17]) can induce an objective response in more than 70% of patients.

Chimeric antigen receptor T-cells (CAR-T) directed against CD30 is being investigated for relapsed Hodgkin lymphoma. If efficacious, this approach may eventually become an alternative to high-dose chemoradiation therapy and autologous hematopoietic cell transplantation.[18]

Management of Complications

Follow-up and Late Complications of Treatment

Most adult patients with Hodgkin lymphoma are cured and experience minimal long-term toxicity from their treatment. However, the risk for certain late effects

TABLE 172-5 MONITORING AFTER SUCCESSFUL PRIMARY TREATMENT OF HODGKIN LYMPHOMA

RISK/PROBLEM	INCIDENCE/RESPONSE
Relapse	Ten to 30% of patients experience relapse. Careful attention should be directed to lymph node sites, especially if previously involved with disease and not treated with radiation. New persistent focal symptoms such as bone pain should be investigated with appropriate laboratory and imaging studies.
Dental caries	Neck or oropharyngeal irradiation may cause decreased salivation. Patients should have regular dental care and should make their dentist aware of the previous irradiation.
Hypothyroidism	After thyroid irradiation at doses sufficient to cure Hodgkin lymphoma, at least 50% of patients eventually become hypothyroid. All patients who have been exposed to neck irradiation should have an annual TSH level determined. Patients whose TSH level becomes elevated should be treated with lifelong thyroxine replacement in doses sufficient to suppress TSH levels to low normal (Chapter 207).
Cardiac complications	Coronary heart disease, especially in patients exposed to mediastinal radiation, anthracyclines, or both.
Infertility	ABVD is not known to cause permanent gonadal toxicity, although temporary oligospermia or irregular menses may persist for 1 to 2 years after treatment. Direct or scatter radiation to gonadal tissue may cause infertility, amenorrhea, or premature menopause, but this adverse event seldom occurs with the current fields used for the treatment of Hodgkin lymphoma. In general, women who continue menstruating are fertile, but men require semen analysis to provide a specific answer.
Secondary neoplasms	Although uncommon, certain secondary neoplasms occur with increased frequency in patients who have been treated for Hodgkin lymphoma: acute myelogenous leukemia; thyroid, breast, lung, gastric, pancreatic, colorectal, and cervical cancers; non-Hodgkin lymphoma; and melanoma. It is appropriate to "be vigilant" for these neoplasms for the remainder of the patient's life because they may have a lengthy induction period.

ABVD = doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine; TSH = thyroid-stimulating hormone.

warrants careful but not intrusive follow-up and selective intervention (Table 172-5). At the conclusion of treatment, a thorough reassessment of the initial sites of lymphoma should be completed to provide post-treatment baseline measurements. Patients should be seen by a specialist knowledgeable in the management of lymphoma, preferably about every 3 months for 2 years, after which follow-up can be switched to the patient's family physician every 6 months for 3 years, then annually. Patients should be strongly encouraged to refrain from smoking, to perform careful breast and skin examinations on a regular basis, and to undergo annual immunization for influenza, immunization for pneumococcus at diagnosis and 5 years after treatment, and immunization for diphtheria and tetanus every 10 years (Chapter 15). Patients who have received radiation to the head or neck area should follow a vigorous program of dental prophylaxis in anticipation of the deleterious effect of reduced saliva production and should have their thyroid-stimulating hormone (TSH) level checked annually in recognition of the 50% risk for eventual hypothyroidism.

Other potential long-term sequelae of the treatment of Hodgkin lymphoma include second malignancies. Radiation therapy–related solid tumors—most commonly nonmelanoma skin cancers, lung, breast, and colorectal malignancies—have a median latency period of more than 14 years after treatment. Chemotherapy-related myelodysplasia (Chapter 167) and acute myeloid leukemia (Chapter 168) are more likely to be caused by alkylating agents that are included in regimens like MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) and BEACOPP, a risk minimized with ABVD, and have shorter latency periods (median of 3 years) after treatment. Despite the trend toward smaller radiation target volumes, lower radiation doses, and less toxic chemotherapy regimens, the risk of solid cancers has not appreciably changed among patients who were treated during the 1990s as compared with patients who were treated during earlier decades.[19] However, more recently treated female survivors of Hodgkin lymphoma appear to have a reduced risk of breast cancer, and the risk of hematologic malignancies has clearly decreased among 5-year survivors who were treated in the most recent study period, probably reflecting the declining use of alkylating agent–based chemotherapy.

Long-term (usually >10 years after treatment) cardiovascular complications include coronary artery disease (related to mediastinal irradiation) and cardiomyopathy (caused by the cardiotoxicity of anthracycline chemotherapy). The median interval between the initial treatment of Hodgkin lymphoma and the development of coronary artery disease is approximately 19 years. There is a linear, no-threshold relationship between mean heart dose of radiation therapy and development of coronary artery disease in survivors of Hodgkin lymphoma, so the reduced radiation exposure to the heart in current radiation therapy protocols should reduce cardiovascular risk in the future. Chemotherapy, particularly alkylating agents in MOPP and BEACOPP but not ABVD regimens, can cause permanent infertility. Long-term survivors of childhood Hodgkin lymphoma (median age at diagnosis of 15 years) are at increased risk for neurocognitive impairment.

Special Problems in the Management of Hodgkin Lymphoma

Hodgkin Lymphoma During Pregnancy

Between 0.5 and 1.0% of cases of Hodgkin lymphoma occur coincident with pregnancy (Chapter 221). When the lymphoma is discovered during pregnancy, it is almost always possible to keep it under control and allow the pregnancy to go to full term.

Standard staging tests (see Table 172-2) should be completed, except that imaging requiring radiation must be minimized. For example, abdominal ultrasonography can identify bulky retroperitoneal disease, and a single posteroanterior radiograph of the chest, with proper shielding, can identify bulky mediastinal disease.

Patients can often continue the pregnancy to term without any treatment of the lymphoma. If symptomatic or progressive disease develops, ABVD chemotherapy can be given in the second and third trimester with very low risk for injuring the fetus. An attractive alternative to multiagent chemotherapy is intermittent single-agent vinblastine, given in the lowest dose that can control symptoms until delivery, followed by a full course of six to eight cycles of multiagent chemotherapy after delivery.

Hodgkin Lymphoma and Acquired Immunodeficiency Syndrome

In patients with HIV infection, the incidence of Hodgkin lymphoma is increased as much as 5- to 10-fold, and the lymphoma manifests differently and pursues a more aggressive natural history (Chapter 359). Hodgkin lymphoma in HIV-positive individuals is almost always associated with Epstein-Barr virus within Hodgkin-Reed-Sternberg cells. The histology is much more likely to be mixed cellularity or lymphocyte depleted. The disease commonly involves extranodal sites, especially the bone marrow. More than 80% of patients have advanced-stage disease, and most patients have B symptoms.

Patients are prone to opportunistic infections, and the interaction of chemotherapeutic agents with other medications may compromise the patient's ability to tolerate treatment. Meticulous attention to drug-drug interactions is required to avoid drug toxicity and adverse pharmacokinetic effects that might compromise the potential for cure.[20] The best approach is a combination of highly active antiretroviral agents (Chapter 357); vigorous supportive care with antiherpetic agents (Chapter 345), antifungal agents (Chapter 307), and neutrophil-stimulating growth factors (Chapter 142); and standard multiagent chemotherapy. With appropriate supportive care, regimens such as ABVD can be delivered. However, more-severe-than-normal toxicity must be anticipated. With appropriate supportive care and careful choice of highly active antiretroviral therapy to avoid drug interactions that compromise delivery of full chemotherapy doses, cure rates and long term survival rates for Hodgkin lymphoma have become comparable to those seen in HIV-negative individuals.[21]

Hodgkin Lymphoma in the Elderly Population

Elderly patients with Hodgkin lymphoma have a worse outcome. For example, the 5-year overall survival rate falls from an average of about 80% in patients younger than age 65 years to less than 50% in patients older than age 65 years as a reflection of the impact of comorbid conditions that may lead to incomplete staging and inadequate adherence to standard treatment protocols. By comparison, elderly patients achieve outcomes equivalent to those of younger patients when they undergo complete staging and receive full doses of planned chemotherapy. The best approach for elderly patients is to attempt to treat them in a manner similar to younger patients, with vigorous supportive care and the addition of neutrophil growth factors such as filgrastim or pegfilgrastim under expert supervision if necessary to enable safe delivery of full doses. In patients over age 70 years or with preexisting pulmonary or cardiac disease, it might be necessary to reduce the dose of bleomycin or omit doxorubicin.

FUTURE DIRECTIONS

The ability to profile multigene expression patterns and identify genetic polymorphisms associated with specific malignancies may provide better insight into the molecular genesis of Hodgkin and other lymphomas. Molecular methods to monitor minimal residual disease, in addition to the current practice of

following only imaging and clinical evaluations, may transform treatment paradigms. Determining levels of circulating tumor DNA holds particular promise for such monitoring. The role of checkpoint inhibitors is likely to evolve as more trials are reported.[22] Therapeutic agents more specifically targeted at the malignant Hodgkin-Reed-Sternberg cells, such as those coupling an antibody to the CD30 antigen with a cellular toxin, hold substantial promise to improve treatment outcomes.

173 PLASMA CELL DISORDERS

S. VINCENT RAJKUMAR

DEFINITION

Plasma cell disorders are neoplastic or potentially neoplastic diseases associated with the clonal proliferation of immunoglobulin-secreting plasma cells (Table 173-1). These disorders are characterized by the secretion of electrophoretically and immunologically homogeneous (monoclonal) proteins that represent intact or incomplete immunoglobulin molecules. Monoclonal proteins are commonly referred to as M proteins, myeloma proteins, or paraproteins.

Syndromes associated with plasma cell disorders and monoclonal proteins include premalignant disorders (monoclonal gammopathy of undetermined significance; MGUS), smoldering multiple myeloma, malignant neoplasms (multiple myeloma, Waldenström macroglobulinemia), as well as disorders primarily related to the unique properties of the secreted monoclonal protein (cryoglobulinemia, immunoglobulin light chain [AL] amyloidosis, light chain deposition disease; see Table 173-1).[1]

Serum Immunoglobulins

Intact immunoglobulins consist of two heavy (H) polypeptide chains of the same class and subclass and two light (L) polypeptide chains of the same type (Chapter 35). The heavy polypeptide chains are designated by Greek letters: γ in immunoglobulin G (IgG), α in immunoglobulin A (IgA), μ in immunoglobulin M (IgM), δ in immunoglobulin D (IgD), and ε in immunoglobulin E (IgE). The light chain types are kappa (κ) and lambda (λ). Both heavy chains and light chains have "constant" and "variable" regions with respect to the amino acid sequence. The class specificity of each immunoglobulin is defined by a series of antigenic determinants on the constant regions of the heavy chains (γ, α, μ, δ, and ε) and the two major classes of light chains (κ and λ). The amino acid sequence in the variable regions of the immunoglobulin molecule corresponds to the active antigen-combining site of the antibody.

In the majority of clonal plasma cell disorders, *intact* immunoglobulin molecules are secreted as monoclonal (M) proteins. In addition, there can also be abnormal secretion of excess monoclonal *free* light chains (FLCs) that are released without being bound to immunoglobulin heavy chains. In some patients, heavy chain expression is completely lost, and only monoclonal free light chains (commonly referred to as Bence Jones proteins) are secreted. Even less frequently, only heavy chains are secreted, resulting in heavy chain diseases (HCDs). Rare patients with multiple myeloma secrete no identifiable immunoglobulin ("nonsecretory myeloma").

Identification of Monoclonal Proteins

Protein electrophoresis of the serum and urine detects M protein as a narrow peak (like a church spire) on the densitometer tracing or as a dense, discrete band on agarose gel (Fig. 173-1). Electrophoresis also permits quantitation of M proteins. Monoclonal light chains (Bence Jones proteins) are rarely seen on serum electrophoresis but are easily detected on urine electrophoresis. Urine electrophoresis requires a 24-hour urine collection.

When a peak or band is first seen on protein electrophoresis, immunofixation of the serum and urine should be performed to identify the heavy and light chain type of the M protein. Immunofixation is also a more sensitive test than protein electrophoresis, and it should always be performed in conjunction with electrophoresis when multiple myeloma or related disorders are first suspected so as to detect small, unmeasurable M proteins that may be missed on electrophoresis. Immunofixation is particularly important in oligosecretory myeloma, primary amyloidosis, and solitary plasmacytoma, as well as after successful treatment of multiple myeloma or macroglobulinemia. In these instances, a small M protein can be concealed within the normal β or γ areas of the electrophoresis gel and may be overlooked. Mass spectrometry can be

following only imaging and clinical evaluations, may transform treatment paradigms. Determining levels of circulating tumor DNA holds particular promise for such monitoring. The role of checkpoint inhibitors is likely to evolve as more trials are reported.[22] Therapeutic agents more specifically targeted at the malignant Hodgkin-Reed-Sternberg cells, such as those coupling an antibody to the CD30 antigen with a cellular toxin, hold substantial promise to improve treatment outcomes.

173 PLASMA CELL DISORDERS

S. VINCENT RAJKUMAR

DEFINITION

Plasma cell disorders are neoplastic or potentially neoplastic diseases associated with the clonal proliferation of immunoglobulin-secreting plasma cells (Table 173-1). These disorders are characterized by the secretion of electrophoretically and immunologically homogeneous (monoclonal) proteins that represent intact or incomplete immunoglobulin molecules. Monoclonal proteins are commonly referred to as M proteins, myeloma proteins, or paraproteins.

Syndromes associated with plasma cell disorders and monoclonal proteins include premalignant disorders (monoclonal gammopathy of undetermined significance; MGUS), smoldering multiple myeloma, malignant neoplasms (multiple myeloma, Waldenström macroglobulinemia), as well as disorders primarily related to the unique properties of the secreted monoclonal protein (cryoglobulinemia, immunoglobulin light chain [AL] amyloidosis, light chain deposition disease; see Table 173-1).[1]

Serum Immunoglobulins

Intact immunoglobulins consist of two heavy (H) polypeptide chains of the same class and subclass and two light (L) polypeptide chains of the same type (Chapter 35). The heavy polypeptide chains are designated by Greek letters: γ in immunoglobulin G (IgG), α in immunoglobulin A (IgA), μ in immunoglobulin M (IgM), δ in immunoglobulin D (IgD), and ε in immunoglobulin E (IgE). The light chain types are kappa (κ) and lambda (λ). Both heavy chains and light chains have "constant" and "variable" regions with respect to the amino acid sequence. The class specificity of each immunoglobulin is defined by a series of antigenic determinants on the constant regions of the heavy chains (γ, α, μ, δ, and ε) and the two major classes of light chains (κ and λ). The amino acid sequence in the variable regions of the immunoglobulin molecule corresponds to the active antigen-combining site of the antibody.

In the majority of clonal plasma cell disorders, *intact* immunoglobulin molecules are secreted as monoclonal (M) proteins. In addition, there can also be abnormal secretion of excess monoclonal *free* light chains (FLCs) that are released without being bound to immunoglobulin heavy chains. In some patients, heavy chain expression is completely lost, and only monoclonal free light chains (commonly referred to as Bence Jones proteins) are secreted. Even less frequently, only heavy chains are secreted, resulting in heavy chain diseases (HCDs). Rare patients with multiple myeloma secrete no identifiable immunoglobulin ("nonsecretory myeloma").

Identification of Monoclonal Proteins

Protein electrophoresis of the serum and urine detects M protein as a narrow peak (like a church spire) on the densitometer tracing or as a dense, discrete band on agarose gel (Fig. 173-1). Electrophoresis also permits quantitation of M proteins. Monoclonal light chains (Bence Jones proteins) are rarely seen on serum electrophoresis but are easily detected on urine electrophoresis. Urine electrophoresis requires a 24-hour urine collection.

When a peak or band is first seen on protein electrophoresis, immunofixation of the serum and urine should be performed to identify the heavy and light chain type of the M protein. Immunofixation is also a more sensitive test than protein electrophoresis, and it should always be performed in conjunction with electrophoresis when multiple myeloma or related disorders are first suspected so as to detect small, unmeasurable M proteins that may be missed on electrophoresis. Immunofixation is particularly important in oligosecretory myeloma, primary amyloidosis, and solitary plasmacytoma, as well as after successful treatment of multiple myeloma or macroglobulinemia. In these instances, a small M protein can be concealed within the normal β or γ areas of the electrophoresis gel and may be overlooked. Mass spectrometry can be

ABSTRACT

Plasma cell disorders encompass a wide spectrum of clinical conditions, including monoclonal gammopathy of undetermined significance (MGUS), smoldering multiple myeloma (SMM), multiple myeloma, solitary plasmacytoma, immunoglobulin light chain amyloidosis, and Waldenström macroglobulinemia. Almost all malignant plasma cell disorders start out as MGUS, which represents the premalignant stage. Although multiple myeloma remains an incurable disease, remarkable progress has been made in risk stratification and in treatment. Established treatments include alkylating agents (melphalan and cyclophosphamide), corticosteroids, immunomodulatory agents (thalidomide, lenalidomide, pomalidomide), proteasome inhibitors (bortezomib, carfilzomib, ixazomib), and monoclonal antibodies (daratumumab, elotuzumab, isatuximab). Major recent advances include chimeric antigen receptor T (CAR-T) cells (idecabtagene vicleucel; ide-cel), ciltacabtagene autoleucel (cilta-cel), bispecific antibodies, and exportin-1 inhibitors (selinexor). Autologous stem cell transplantation continues to be an important therapeutic option.

used instead of immunofixation to identify the M protein more accurately (E-Figs. 173-1 and 173-2).

Monoclonal proteins must be distinguished from an excess of polyclonal immunoglobulins (one or more heavy chain types and both κ and λ light chains, usually limited to the γ region), which produce a broad-based peak or broad band (Fig. 173-2). This finding is associated with chronic infectious or inflammatory states.

Detection of Serum Free Light Chains

The serum free light chain assay measures the level of free κ and λ immunoglobulin light chains (i.e., light chains that are not bound to intact immunoglobulin). An abnormal κ/λ free light chain ratio (normal range, 0.26 to 1.65) indicates a significant excess of one light chain type versus the other and is interpreted as representing a monoclonal elevation of the corresponding light chain type. The serum free light chain assay is more sensitive than electrophoresis or immunofixation in detecting free monoclonal light chains and is useful in the diagnostic evaluation of plasma cell disorders and in risk stratification.

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

DEFINITION

Monoclonal gammopathy of undetermined significance (MGUS; formerly called *benign monoclonal gammopathy*) is a premalignant clonal plasma cell disorder characterized by the presence of a serum M protein in persons who lack evidence of multiple myeloma, macroglobulinemia, amyloidosis, or other related diseases. MGUS is defined by a serum M protein concentration lower than 3 g/dL, less than 10% clonal plasma cells in the bone marrow, and absence of myeloma-defining events. The main clinical significance of MGUS is its lifelong risk of transformation to myeloma or related malignancy at a fixed but unrelenting rate of 1% per year.[2] There are three major types of MGUS: IgM MGUS, non-IgM MGUS, and light chain MGUS (Table 173-2).

EPIDEMIOLOGY

Most patients in whom a serum M protein is detected have MGUS (E-Fig. 173-3). The prevalence of MGUS in the general population increases with age, from approximately 1% in persons 50 to 60 years old to greater than 5% in those older than 70 years. The age-adjusted prevalence is higher in males than in females and is twice as high in Blacks compared with Whites (E-Table 173-1). The prevalence of MGUS and of multiple myeloma is increased among blood relatives of individuals with monoclonal gammopathies.

PATHOBIOLOGY

The etiology of MGUS is unknown, but age, male gender, family history, immunosuppression, and exposure to certain pesticides are known risk factors. It is hypothesized that infection, inflammation, or other antigenic stimuli, acting in concert with the development of cytogenetic abnormalities in the plasma cells, are the initiating pathogenetic events in most patients. Approximately 40% of MGUS is associated with plasma cell translocations involving the immunoglobulin heavy chain (IgH) locus on chromosome 14q32 (IgH translocated MGUS), 40% with trisomies involving odd-numbered chromosomes (hyperdiploid MGUS), 15% with both trisomies and IgH translocations, and the remaining with other cytogenetic abnormalities. The primary IgH translocations seen in MGUS commonly involve one of five recurrent partner chromosome loci: 11q13 (*CCND1* [cyclin D1 gene]), 4p16.3 (*FGFR-3* and *MMSET*), 6p21 (*CCND3* [cyclin D3 gene]), 16q23 (*c-maf*), and 20q11 (*mafB*). On flow cytometry, normal plasma cells are preserved and reside alongside the clonal cells.

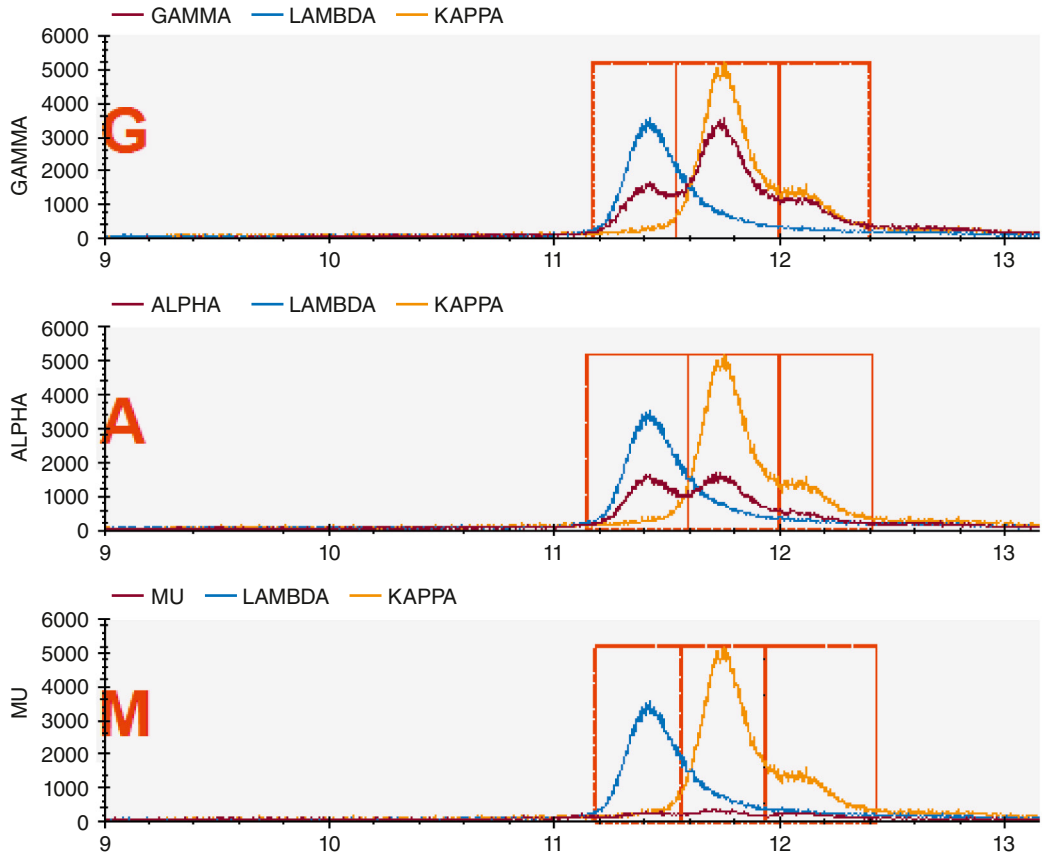
CLINICAL MANIFESTATIONS

MGUS is asymptomatic and is usually diagnosed incidentally on laboratory testing. Patients with MGUS progress to multiple myeloma or related malignancy at a rate of approximately 1% per year. Patients with IgM MGUS are at risk of progression to Waldenström macroglobulinemia, while patients with non-IgM MGUS and light chain MGUS are at risk of progression to multiple myeloma. All forms of MGUS carry a risk of progression to AL amyloidosis.

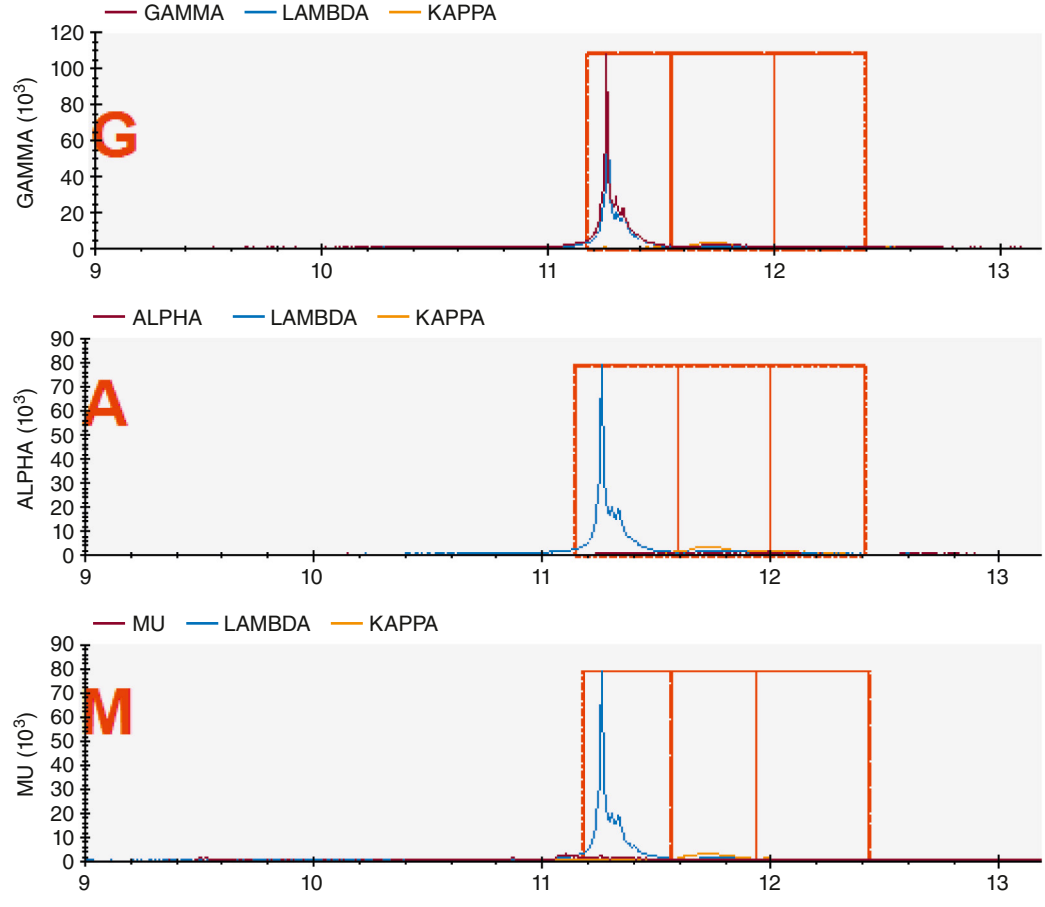
DIAGNOSIS

MGUS represents a limited, nonmalignant expansion of monoclonal plasma cells. MGUS is differentiated from multiple myeloma and smoldering multiple myeloma by the level of the M protein, the percentage of plasma cells in the bone marrow, and the presence or absence of anemia, renal failure, hypercalcemia, or lytic bone lesions (Table 173-2).[3] Because anemia and renal insufficiency are relatively common in the elderly population with MGUS, the causes of these conditions should be carefully investigated with adequate laboratory studies. Only patients with strong evidence of end-organ damage thought to be directly related to a plasma cell disorder can be considered to have myeloma or a related malignancy.

Although a reduction in the levels of the immunoglobulin classes other than M protein (i.e., the normal polyclonal or background immunoglobulins) is more frequently seen in multiple myeloma or Waldenström macroglobulinemia, such reductions also occur in almost 40% of patients with MGUS.



E-FIGURE 173-1. **Mass spectrometry to identify monoclonal protein.** Mass spectrometry shows normal results with total kappa light chain *(orange)* and total lambda light chain *(blue)* distribution repeated in all three spectra. The light chains associated with IgG *(top)*, IgA *(middle)*, and IgM *(bottom)* are displayed in red.



E-FIGURE 173-2. **Mass spectrometry to identify monoclonal protein.** Mass spectrometry showing overlapping peaks in the total lambda light chain distribution *(blue)* and in the light chains associated with IgG. This result is consistent with an IgG lambda paraprotein.

Modified from Landgren O, et al. Prevalence of myeloma precursor state monoclonal gammopathy of undetermined significance (MGUS) in 12,309 individuals 10 to 49 years old: a population-based study from the National Health and Nutritional Examination Survey. *Blood Cancer J.* 2017;7:e618.

TABLE 173-2 CRITERIA FOR THE DIAGNOSIS OF PLASMA CELL DISORDERS

DISORDER	DISEASE DEFINITION
IgM monoclonal gammopathy of undetermined significance (IgM MGUS)	All three criteria must be met: 1. Serum IgM monoclonal protein <3 g/dL 2. Bone marrow lymphoplasmacytic infiltration <10% 3. No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder
Non-IgM monoclonal gammopathy of undetermined significance (MGUS)	All three criteria must be met: 1. Serum monoclonal protein (non-IgM type) <3 g/dL 2. Clonal bone marrow plasma cells <10%* 3. Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) that can be attributed to the plasma cell proliferative disorder
Light chain MGUS	All criteria must be met: 1. Abnormal FLC ratio (<0.26 or >1.65) 2. Increased level of the appropriate involved light chain (increased κ FLC in patients with ratio >1.65 and increased λ FLC in patients with ratio <0.26) 3. No immunoglobulin heavy chain expression on immunofixation 4. Absence of end-organ damage that can be attributed to the plasma cell proliferative disorder 5. Clonal bone marrow plasma cells <10% 6. Urinary monoclonal protein <500 mg/24 h
Smoldering multiple myeloma	Both criteria must be met: 1. Serum monoclonal protein (IgG or IgA) ≥3 g/dL, or urinary monoclonal protein ≥500 mg per 24 h and/or clonal bone marrow plasma cells 10-60% 2. Absence of myeloma-defining events or amyloidosis

Multiple myeloma	Both criteria must be met:
	1. Clonal bone marrow plasma cells ≥10% or biopsy-proven bony or extramedullary plasmacytoma
	2. Any one or more of the following myeloma-defining events:
	• Evidence of end-organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically:
	  • Hypercalcemia: serum calcium >0.25 mmol/L (>1 mg/dL) higher than the upper limit of normal or >2.75 mmol/L (>11 mg/dL)
	  • Renal insufficiency: creatinine clearance <40 mL per minute or serum creatinine >177 μmol/L (>2 mg/dL)
	  • Anemia: hemoglobin value of >2 g/dL below the lower limit of normal or a hemoglobin value <10 g/dL
	  • Bone lesions: one or more osteolytic lesions on skeletal radiography, computed tomography (CT), or positron emission tomography-CT (PET-CT)
	• Clonal bone marrow plasma cell percentage ≥60%
	• Involved: uninvolved serum free light chain (FLC) ratio ≥100 (involved free light chain level must be ≥100 mg/L)
	• >1 focal lesions on magnetic resonance imaging (MRI) studies (at least 5 mm in size)

Solitary plasmacytoma	All four criteria must be met: 1. Biopsy-proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells 2. Normal bone marrow with no evidence of clonal plasma cells 3. Normal skeletal survey and MRI (or CT) of spine and pelvis (except for the primary solitary lesion) 4. Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, or bone lesions (CRAB) that can be attributed to a lymphoplasma cell proliferative disorder
Solitary plasmacytoma with minimal marrow involvement†	All four criteria must be met: 1. Biopsy-proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells 2. Clonal bone marrow plasma cells <10% 3. Normal skeletal survey and MRI (or CT) of spine and pelvis (except for the primary solitary lesion) 4. Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, or bone lesions (CRAB) that can be attributed to a lymphoplasma cell proliferative disorder

*A bone marrow can be deferred in patients with low-risk MGUS (IgG type, M protein <1.5 g/dL, normal free light chain ratio) in whom there are no clinical features concerning for myeloma.
†Solitary plasmacytoma with 10% or more clonal plasma cells is considered multiple myeloma.
FLC = free light chain; Ig = immunoglobulin; MRI = magnetic resonance imaging.

Association of MGUS with Other Diseases

MGUS is associated with numerous diseases. However, because 3% of the general population older than 50 years has MGUS, it is often difficult to determine whether these reported associations are causal or coincidental. Associations that have been verified based on epidemiologic studies include peripheral neuropathy (Chapter 388), proliferative glomerulonephritis, deep vein thrombosis (Chapter 68), osteoporosis (Chapter 225), and lymphoproliferative disorders (Chapter 171). A secondary form of MGUS also occurs with immunosuppression after organ transplantation (Chapter 38) and autologous or allogeneic stem cell transplantation (Chapter 163). M proteins also occur in the sera of some patients with CLL (Chapter 169) but have no recognizable effect on the clinical course.

Approximately 5% of patients with sensorimotor peripheral neuropathy of unknown cause (Chapter 388) have an associated monoclonal gammopathy (monoclonal gammopathy–associated peripheral neuropathy).[4] Patients with IgM MGUS–associated peripheral neuropathy have a slowly progressive distal acquired demyelinating symmetric (DADS) presentation, with predominantly sensory symptoms beginning in the distal ends of the extremities and extending proximally. In contrast, non-IgM MGUS neuropathy may present similar to chronic inflammatory demyelinating polyneuropathy (CIDP) with both proximal and distal involvement and with more motor symptoms. A causal relationship between MGUS and peripheral neuropathy is usually assumed in younger patients and those without other conditions known to cause neuropathy in whom the neuropathy is severe and progressive. Therapeutic approaches include intravenous immunoglobulin or rituximab for IgM monoclonal proteins and plasmapheresis or prednisone for non-IgM monoclonal proteins.

Monoclonal gammopathy is also felt to be the underlying cause of approximately 50% of idiopathic proliferative glomerulonephritis (Chapter 107), including membranoproliferative glomerulonephritis and C3 glomerulopathy. Certain skin disorders are also known to be associated with MGUS. Lichen myxedematosus (papular mucinosis, scleromyxedema) (Chapter 407) is associated with an IgG γ protein. Pyoderma gangrenosum and necrobiotic xanthogranuloma are other associated skin disorders.

TREATMENT

No treatment is necessary for MGUS (Fig. 173-3).[5] A baseline bone marrow biopsy and bone imaging can be omitted in patients who appear clinically to have low-risk, uncomplicated MGUS, small IgM MGUS, or light chain MGUS with a free light chain ratio less than 8. Bone imaging can also be omitted in patients who have IgM MGUS and in whom bone disease is not suspected. Low-risk patients (Table 173-3) should be evaluated in 6 months and, if stable, require no further follow-up until symptoms suggestive of myeloma or related disorders occur. In all other patients with MGUS, electrophoresis, serum free light chains, complete blood count, and creatinine and calcium levels should be repeated at 6 months and, if stable, yearly thereafter.

PROGNOSIS

Differentiating a patient with MGUS in whom the disorder will remain stable for life from one in whom multiple myeloma, macroglobulinemia, or a related disorder will eventually develop is difficult when the M protein is first recognized. The size and type of the M protein at diagnosis of MGUS and an abnormal serum free light chain ratio are prognostic factors for progression (see Table 173-3).[6] Overall, about one third of patients progress to a symptomatic monoclonal gammopathy over 10 or more years.[7]

BICLONAL GAMMOPATHIES

Biclonal gammopathies occur in at least 5% of patients with clonal plasma cell disorders. A biclonal gammopathy of undetermined significance (analogous to MGUS) accounts for about two thirds of such patients. The remainder have multiple myeloma, macroglobulinemia, or other lymphoproliferative diseases. Rarely, triclonal gammopathies may occur.

MULTIPLE MYELOMA

DEFINITION

Multiple myeloma is a malignancy of plasma cells characterized by bone marrow infiltration and extensive skeletal destruction resulting in anemia, bone pain, and fractures. Multiple myeloma (commonly referred to as *myeloma*) is defined by the presence of 10% or more clonal plasma cells on bone marrow examination, M protein in serum or urine (except in the case of nonsecretory myeloma), and evidence of one or more myeloma-defining events (see Table 173-2). Patients with multiple myeloma must be differentiated from those with MGUS and smoldering multiple myeloma.[8]

EPIDEMIOLOGY

Multiple myeloma accounts for 1% of all malignant disease and slightly more than 10% of hematologic malignancies in the United States. The annual

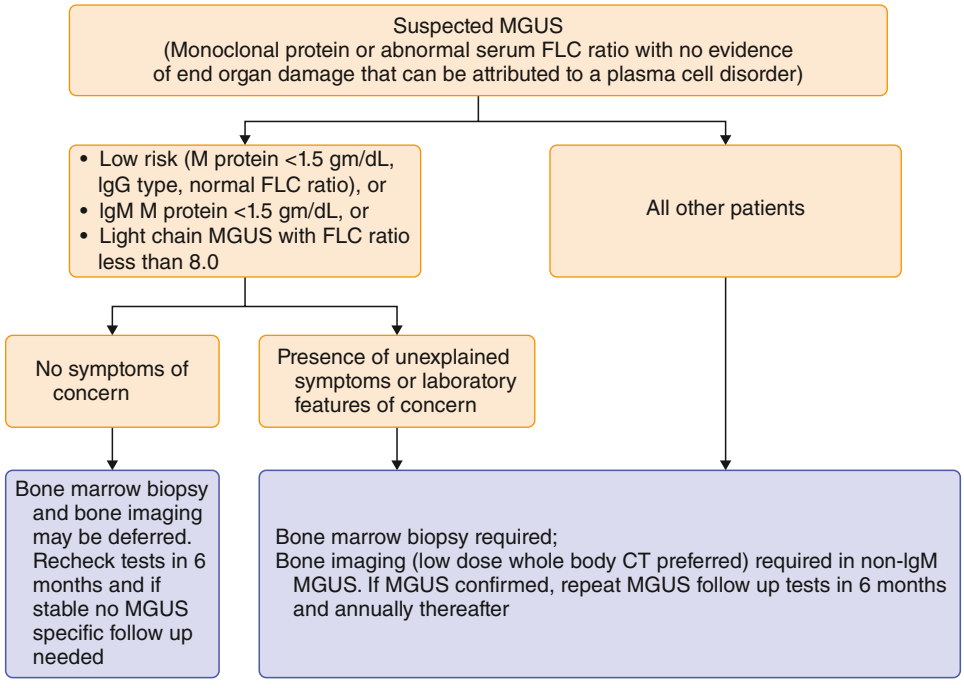

FIGURE 173-3. Approach to diagnosis and management of monoclonal gammopathy of undetermined significance. CT = computed tomography; FLC = free light chain ration; MGUS = monoclonal gammopathy of undermined significance.

TABLE 173-3 RISK OF PROGRESSION OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE TO MYELOMA OR RELATED DISORDERS

RISK GROUP	RELATIVE RISK	CUMULATIVE ABSOLUTE RISK OF PROGRESSION AT 20 YR (%)*	CUMULATIVE ABSOLUTE RISK OF PROGRESSION AT 20 YR ACCOUNTING FOR DEATH AS A COMPETING RISK (%)†
Low risk: serum M protein <1.5 g/dL, IgG subtype, normal free light chain ratio (0.26-1.65)	1	5	2
Low-intermediate risk: any one factor abnormal	5.4	21	10
High-intermediate risk: any two factors abnormal	10.1	37	18
High risk: all three factors abnormal	20.8	58	27

*Estimates in this column represent the risk of progression, assuming that patients do not die of other causes during this period.
†Estimates in this column represent the risk of progression calculated by using a model that accounts for the fact that patients can die of unrelated causes during this time.
Ig = immunoglobulin.
Adapted from Rajkumar SV, Kyle RA, Therneau TM, et al. Serum free light chain ratio is an independent risk factor for progression in monoclonal gammopathy of undetermined significance (MGUS). *Blood*. 2005;106:812-817.

incidence of multiple myeloma is approximately 4 per 100,000. The incidence of multiple myeloma in Blacks is almost twice that in Whites. Multiple myeloma is slightly more common in men than in women. The median age of patients at the time of diagnosis is about 65 years; only 2% of patients are younger than 40.

PATHOBIOLOGY

The cause of multiple myeloma is unclear. Exposure to radiation, benzene, and other organic solvents, herbicides, and insecticides may play a role. Multiple myeloma has been reported in familial clusters of two or more first-degree relatives and in identical twins.

Almost all cases of myeloma evolve from a premalignant MGUS phase, although the MGUS is clinically recognized before the diagnosis of myeloma in only a small minority of patients. The progression of MGUS to myeloma suggests a simple, random, two-hit genetic model of malignancy in which the risk of progression is fixed (approximately 1% per year) regardless of the duration of MGUS. Unfortunately, the precise mechanisms of progression are unknown, although several potentially pathogenetic abnormalities have been described in the clonal plasma cells. The two main events associated with progression of MGUS to multiple myeloma appear to be *RAS* mutations and *MYC* abnormalities. Deletions involving 17p and 1p and amplification of 1q occur with disease progression in multiple myeloma and are associated with adverse prognosis. These changes cause dysregulation of the NF-κB and other signaling pathways. Normal plasma cell differentiation is also affected. Changes in the bone marrow microenvironment likely play a major role in the pathogenesis, including induction of angiogenesis and abnormal paracrine loops involving cytokines such as interleukin-6 (IL-6), which serves as a major growth factor for plasma cells.

The lytic bone lesions, osteopenia, hypercalcemia, and pathologic fractures in patients with myeloma are a result of abnormal osteoclast activity induced by the neoplastic plasma cells, as well as inhibition of osteoblast differentiation. Osteoclasts are activated by stimulation of the transmembrane receptor RANK (receptor activator of nuclear factor κB), which belongs to the tumor necrosis factor (TNF) receptor superfamily. The ligand for this receptor (RANKL) also has a decoy receptor, osteoprotegerin (OPG). In myeloma, there is an increase in RANKL expression by osteoblasts (and possibly plasma cells), accompanied by a reduction in the level of OPG. The resultant increase in the RANKL/OPG ratio causes osteoclast activation and increased bone resorption and turnover (Chapter 225). Other factors that may play a role in osteoclast activation include increased levels of macrophage inflammatory protein–1-alpha (MIP-1-alpha), stromal derived factor alpha (SDF-alpha), IL (interleukin)-3, IL-1 beta, and IL-6. In addition to these changes that promote osteoclast activation, simultaneous suppression of osteoblasts is mediated by increased levels of IL-3, IL-7, and dickkopf 1 (DKK1). This combination leads to the pure osteolytic bone disease that is the hallmark of multiple myeloma.

Cytogenetic Abnormalities

As discussed earlier (see Pathobiology of MGUS), primary translocations involving the IgH loci (chromosome 14q32) are seen in up to 40% of patients with multiple myeloma (IgH-translocated or nonhyperdiploid myeloma). Approximately 40% of patients do not have IgH translocations but have evidence of trisomies (hyperdiploid myeloma), 15% have both IgH translocations and trisomies, and 5% have other abnormalities. Although IgH translocations and trisomies originate at the MGUS stage, the response to therapy and prognosis of myeloma are affected by the specific underlying abnormality (Table 173-4). Besides these primary cytogenetic abnormalities, other abnormalities (termed secondary cytogenetic abnormalities) occur as late events during the course of symptomatic myeloma; these include deletion of 17p, deletion of 1p, and amplification of 1q.

CLINICAL MANIFESTATIONS

Many patients are asymptomatic because they are detected early based on incidental laboratory testing. Smoldering (asymptomatic) multiple myeloma is defined by the presence of an M protein level greater than 3 g/dL in serum or 10 to 60% clonal plasma cells in bone marrow in the absence of anemia, renal insufficiency, hypercalcemia, or skeletal lesions. Clinically, patients with smoldering multiple myeloma are similar to patients who have MGUS but carry a much higher risk for progression to myeloma or a related malignancy: 10% per year for the first 5 years, 5% per year for the next 5 years, and 1 to 2% per year thereafter. Even patients who meet the full criteria for multiple myeloma may be asymptomatic and be detected only by an evaluation of laboratory abnormalities.

TABLE 173-4 STAGING AND PROGNOSTIC FACTORS IN MULTIPLE MYELOMA

STAGE/RISK FACTOR
Stage I (serum albumin >3.5, serum beta-2-microglobulin <3.5, no high-risk cytogenetics, and normal serum lactate dehydrogenase level)
Stage II (neither stage I nor stage III)
Stage III (serum beta-2-microglobulin >5.5 and either high-risk cytogenetics [t(4;14), t(14;16), or del(17p)] or elevated serum lactate dehydrogenase level)
High-risk myeloma (any one of the following): Translocations of t(14;16), t(14;20), t(4;14) Deletion of 17p Amplification of 1q p53 mutation
Standard-risk myeloma Translocations of t(11;14), t(6;14) Trisomies
Poor performance status
Increased circulating plasma cells
Plasmablastic morphology

History

Bone pain, particularly in the back or chest and less often in the extremities, is present at the time of diagnosis in more than two thirds of patients. The patient's height may be reduced by several inches because of vertebral collapse. Weakness and fatigue are common and are often associated with anemia. The incidence of infections is increased in patients with multiple myeloma. The propensity for infection results from impairment of the antibody response, deficiency of normal immunoglobulins, and neutropenia. Myeloma patients also have an increased risk of deep vein thrombosis, although some myeloma treatments (e.g., lenalidomide) may themselves cause thrombosis. Other symptoms may result from renal insufficiency, hypercalcemia, nephrotic syndrome, radiculopathy, or AL amyloidosis (Chapter 174).

Physical Examination

Pallor is the most frequent physical finding in patients with multiple myeloma. The liver is palpable in about 5% of patients and the spleen in only 1%. Tenderness may be noted at sites of bone involvement. Radiculopathy may be caused by spinal compression fractures. Occasionally, extramedullary plasmacytomas are palpable.

DIAGNOSIS

Laboratory Findings

A normocytic, normochromic anemia (Chapter 144) is present initially in approximately 75% of patients, but it eventually occurs in nearly every patient with multiple myeloma. Serum protein electrophoresis shows an M protein in 80% of patients. With the increased sensitivity of serum immunofixation, an M protein can be detected in 93% of patients. When these serum studies are combined with urine electrophoresis plus immunofixation, an M protein can be detected in 97% of patients with myeloma.[9] The serum free light chain assay is more convenient and can be used in place of urine studies in the diagnostic evaluation. The type of M protein is IgG in 52%, IgA in 21%, light chain only in 16%, IgD in 2%, and biclonal gammopathy in 2%; the light chain type is κ in 65% of cases and λ in 35%. In 3% of patients, no secreted M protein can be identified; these patients are considered to have nonsecretory myeloma.

In the bone marrow, clonal plasma cells account for greater than 10% of all nucleated cells in 96% of patients (Fig. 173-4 and E-Figs.173-4 and 173-5). In 4% of patients, bone marrow examination shows less than 10% plasma cells, even though the patient otherwise meets the criteria for myeloma; because bone marrow involvement in myeloma may be focal rather than diffuse, repeated bone marrow examinations or biopsy of a discrete bone or extramedullary lesion may be required. In most cases, the plasma cells in myeloma are cytoplasmic Ig^+, $CD38^+$, $CD45^-$, $CD138^+$, and CD 56^+. Only 20% express CD20. The clonality of the plasma cells is established using the κ/λ ratio by immunohistochemistry or flow cytometry (E-Fig. 173-6). The κ/λ ratio is abnormal in myeloma (either >4 : 1, indicating a clonal κ population, or <1 : 2, indicating a clonal λ population). This is helpful for differentiating monoclonal plasma cell proliferation in multiple myeloma from reactive plasmacytosis.

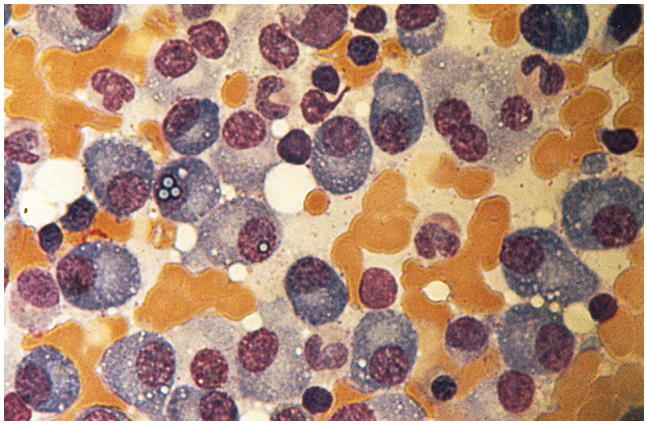

FIGURE 173-4. Multiple myeloma. A bone marrow aspirate shows a predominance of plasma cells.

FIGURE 173-5. Skull radiograph showing multiple lytic lesions.

Radiologic Findings

Conventional radiographic studies reveal abnormalities consisting of punched-out lytic lesions (Fig. 173-5), osteoporosis, or fractures in nearly 80% of patients. The vertebrae, skull, thoracic cage, pelvis, and proximal ends of the humerus and femur are the most frequent sites of involvement. Conventional radiographs are not sensitive, and low-dose whole body computed tomography and positron emission tomography (PET) are now the preferred imaging modalities to assess bone disease in multiple myeloma (Fig. 173-6).[10] Magnetic resonance imaging (MRI) is useful in patients in whom there is doubt about the magnitude of the disease burden and in those who have spinal involvement.

Organ Involvement

Renal

Renal insufficiency, defined as a creatinine level greater than 2 mg/dL, is observed in 20% of patients with multiple myeloma at diagnosis. The two major causes of renal insufficiency are light chain cast nephropathy *(myeloma kidney)* and hypercalcemia. Light chain cast nephropathy is characterized by the presence of large, waxy, laminated casts in the distal and collecting tubules. The casts are composed mainly of precipitated monoclonal light chains. The extent of cast formation correlates directly with the amount of free urinary light chain and with the severity of renal insufficiency. Hypercalcemia, which is present in 15 to 20% of patients initially, is a major and treatable cause of renal insufficiency. It results from destruction of bone. Other contributing factors include dehydration and hyperuricemia.

Besides light chain cast nephropathy and hypercalcemia, there are other mechanisms by which renal dysfunction can occur in myeloma and related plasma cell disorders. For example, light chain amyloidosis (Chapter 174) occurs in nearly 10% of patients with myeloma and may produce nephrotic syndrome, renal insufficiency, or both. Acquired Fanconi syndrome (Chapter 108), characterized by proximal tubular dysfunction, results in glycosuria, phosphaturia, and aminoaciduria. Deposition of monoclonal light chains in the renal glomerulus (light chain deposition disease) may also produce renal insufficiency and nephrotic syndrome. Monoclonal gammopathy–associated proliferative glomerulonephritis presents with hematuria and renal insufficiency.

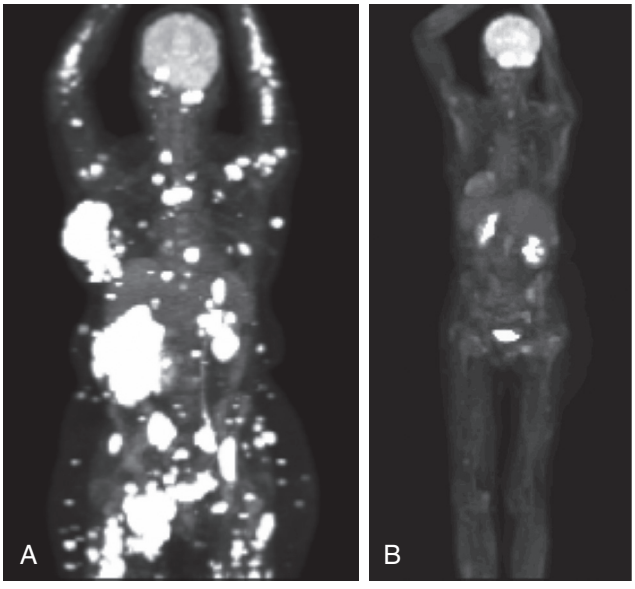

FIGURE 173-6. Positron emission tomography in multiple myeloma. A, Extensive bony and extramedullary disease. **B,** Significant improvement after systemic chemotherapy for myeloma.

Neurologic

Radiculopathy (Chapter 369), which is the single most frequent neurologic complication of multiple myeloma, usually occurs in the thoracic or lumbosacral area and results from compression of the nerve by the vertebral lesion or by the collapsed bone itself. Compression of the spinal cord occurs in up to 10% of patients. Peripheral neuropathy (Chapter 388) is uncommon in multiple myeloma and, when present, is generally caused by amyloidosis. Rarely, myeloma cells diffusely infiltrate the meninges. Intracranial plasmacytomas almost always represent extensions of myelomatous lesions of the skull. True involvement of the central nervous system is rare and is associated with poor prognosis.

Other Systemic Involvement

Hepatic infiltration, pleural effusions, or ascites suggests progression to plasma cell leukemia. Similarly the development of multiple extramedullary plasmacytomas is also a sign of more aggressive disease biology.

TREATMENT

Smoldering Multiple Myeloma

Treatment for patients with smoldering multiple myeloma depends on the risk of progression. Risk factors for progression include serum monoclonal protein greater than 2 gm/dL, serum free light chain ratio greater than 20, and bone marrow plasma cells greater than 20%. Patients with zero or one risk factor are considered to have low- or intermediate-risk smoldering multiple myeloma, respectively. Patients with two or three risk factors are considered to have high-risk smoldering multiple myeloma.[11]

Patients with low- or intermediate-risk smoldering multiple myeloma should not be treated until evidence of multiple myeloma develops (Fig. 173-7).[12,13] The standard of care for low- and intermediate-risk smoldering multiple myeloma is observation every 3 to 4 months. In patients with high-risk smoldering multiple myeloma, therapy for approximately 2 years with lenalidomide (25 mg on days 1 to 21 of a 28-day cycle) or with lenalidomide plus low-dose dexamethasone (40 mg once per week) can significantly reduce the risk of progression to symptomatic multiple myeloma, the development of end-organ damage,[A1] and overall mortality.[A2]

Multiple Myeloma

The approach to the treatment of multiple myeloma (Fig. 173-8) is increasingly targeted and personalized under expert supervision.[14] Response to therapy and minimal residual disease assessment is assessed using standard International

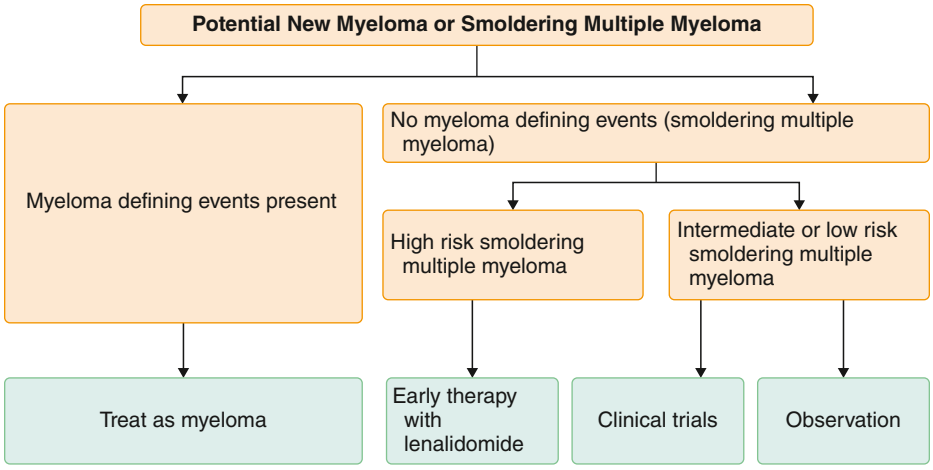

FIGURE 173-7. **Approach to the management of smoldering multiple myeloma.**

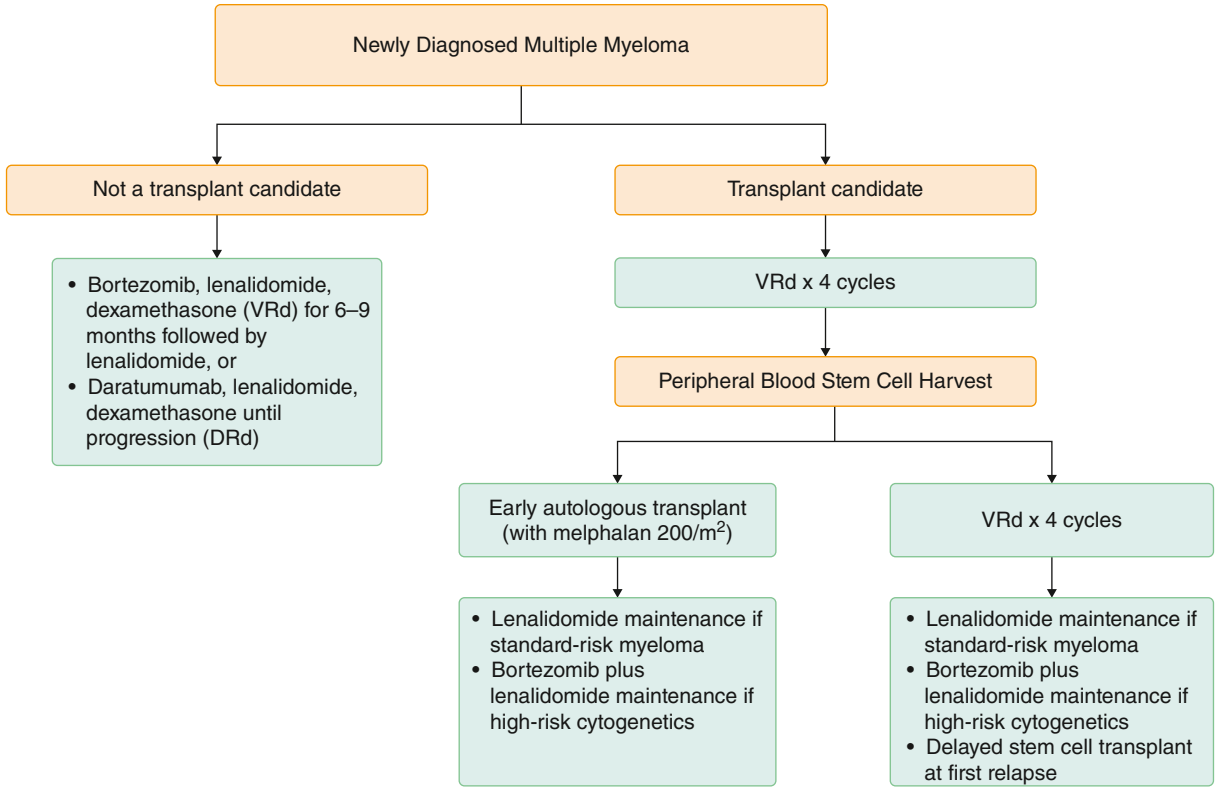

FIGURE 173-8. **Approach to newly diagnosed multiple myeloma.** DRd = daratumumab, lenalidomide, and dexamethasone; VRd = bortezomib-lenalidomide-dexamethasone.

Myeloma Working Group criteria.[15] Although achieving a minimal residual disease-negative state is associated with better survival, therapy usually is not changed based on the presence of minimal residual disease.

Initial Therapy of Patients Who Are Candidates for Autologous Stem Cell Transplantation

In the approximately 50% of patients with newly diagnosed multiple myeloma who are considered candidates for autologous stem cell transplantation based on good performance status, no or limited comorbid conditions, and younger physiologic age (<65 to 70 years), autologous peripheral blood stem cell transplantation (Chapter 163) with high-dose chemotherapy improves overall survival in comparison to conventional chemotherapy. Autologous transplantation is not curative, but it prolongs event-free and overall survival.[16]

Initial therapy typically consists of bortezomib, lenalidomide, and dexamethasone (VRd) for approximately 3 to 4 months followed by stem cell collection,[A3] but adding daratumumab may provide even better results[A4,A5] and can be considered in patients with high-risk myeloma. Alternative induction regimens include the combination of daratumumab, lenalidomide, and dexamethasone (DRd)[A6] or the combination of bortezomib, cyclophosphamide, and dexamethasone (VCD) (Table 173-5). Lenalidomide plus low-dose dexamethasone (40 mg once a week) is associated with superior overall survival compared with lenalidomide and high-dose dexamethasone (40 mg on days 1 to 4, 9 to 12, and 17 to 20). Toxicities of lenalidomide include deep vein thrombosis, and all patients must be treated with prophylactic aspirin or an anticoagulant.

After induction therapy, peripheral blood stem cells adequate for one to two stem cell transplants are collected with the use of granulocyte colony-stimulating factor with or without plerixafor or cyclophosphamide to aid in mobilization. Autologous stem cell transplantation (Chapter 163) is performed with melphalan 200 mg/m^2 as the conditioning regimen, followed by infusion of peripheral blood stem cells.

Early stem cell transplantation is often preferred[A7] because its mortality is low (<1%), and it avoids the inconvenience, cost, and potential side effects of prolonged chemotherapy. However, an equally good alternative approach in patients with standard-risk newly diagnosed myeloma is to delay transplantation until the first relapse.[A8] With this latter strategy, stem cells are collected and cryopreserved for future use after initial therapy. Patients then continue

TABLE 173-5 SELECTED REGIMENS FOR THE TREATMENT OF MULTIPLE MYELOMA

REGIMEN	USUAL DOSING SCHEDULE*
Bortezomib-cyclophosphamide-dexamethasone (VCd or CyBord)	Cyclophosphamide 300 mg/m^2 orally on days 1, 8, 15 and 22 Bortezomib 1.3 mg/m^2 intravenously on days 1, 8, 15, 22 Dexamethasone 40 mg orally on days on days 1, 8, 15, 22 Repeated every 4 wk
Bortezomib-lenalidomide-dexamethasone (VRd)	Bortezomib 1.3 mg/m^2 intravenous days 1, 8, 15 Lenalidomide 25 mg oral days 1-14 Dexamethasone 20 mg on day of and day after bortezomib (or 40 mg days 1, 8, 15, 22) Repeated every 3 wk
Carfilzomib-lenalidomide-dexamethasone (KRd)	Carfilzomib 20 mg/m^2 on cycle 1 and 27 mg/m^2 on subsequent cycles, intravenously on days 1, 2, 8, 9, 15, 16 Lenalidomide 25 mg oral days 1-21 Dexamethasone 20 mg on day of and day after bortezomib (or 40 mg days 1, 8, 15, 22) Repeated every 4 wk
Daratumumab-lenalidomide-dexamethasone (DRd)	Daratumumab 16 mg/kg intravenously weekly for 8 wk, and then every 2 wk for 4 mo, and then once monthly Lenalidomide 25 mg oral days 1-21 Dexamethasone 40 mg days 1, 8, 15, 22 Lenalidomide-dexamethasone repeated in usual schedule every 4 wk
Daratumumab-bortezomib-lenalidomide-dexamethasone (DVRd)	Daratumumab 16 mg/kg intravenously weekly × 8 wk, and then every 2 wk for 4 mo, and then once monthly Bortezomib 1.3 mg/m^2 intravenous days 1, 8, 15 Lenalidomide 25 mg oral days 1-14 Dexamethasone 40 mg days 1, 8, 15, 22 Bortezomib, lenalidomide, dexamethasone repeated every 3 wk
Elotuzumab-lenalidomide-dexamethasone (ERd)	Elotuzumab 10 mg/kg intravenously weekly × 8 wk, and then every 2 wk Lenalidomide 25 mg oral days 1-21 Dexamethasone 40 mg days 1, 8, 15, 22 Lenalidomide-dexamethasone repeated in usual schedule every 4 wk
Ixazomib-lenalidomide-dexamethasone (IRd)	Ixazomib 4 mg oral days 1, 8, 15 Lenalidomide 25 mg oral days 1-21 Dexamethasone 40 mg days 1, 8, 15, 22 Repeated every 4 wk
Daratumumab-bortezomib-dexamethasone (DVd)	Daratumumab 16 mg/kg intravenously weekly × 8 wk, and then every 2 wk for 4 mo, and then once monthly Bortezomib 1.3 mg/m^2 subcutaneously on days 1, 8, 15, 22 Dexamethasone 20 mg on day of and day after bortezomib or 40 mg days 1, 8, 15, 22 Bortezomib-dexamethasone repeated in usual schedule every 4 wk

*All doses need to be adjusted for performance status, renal function, blood counts, and other toxicities; doses of dexamethasone and/or bortezomib recommended have been reduced based on subsequent data showing lower toxicity and similar efficacy with reduced doses. Daratumumab can be given using a subcutaneous formulation instead of the intravenous route. Duration of therapy for all regimens varies under expert supervision depending on the disease phase.

Modified from Rajkumar SV. Multiple myeloma: 2020 update on diagnosis, risk-stratification, and management. *Am J Hematol*. 2020;95:548-567.

initial therapy for a few more months, followed by maintenance. Delayed stem cell transplantation is performed at the time of first relapse. The choice of early versus delayed transplantation is usually based on the patient's preferences and other clinical conditions, but early transplantation is often recommended.

Following stem cell transplantation, the long-term outcome is improved by lenalidomide maintenance (10 mg per day). In high-risk multiple myeloma, bortezomib maintenance is administered every 2 weeks in combination with lenalidomide (see Table 173-4 for definitions of standard and high-risk myeloma).

Allogeneic Bone Marrow Transplantation

Allogeneic transplantation for myeloma is best performed in the context of clinical trials or as second-line salvage therapy in selected high-risk patients who are willing to accept the high treatment-related mortality rate associated with the procedure.[17]

Initial Therapy of Patients Who Are Not Candidates for Transplantation

Approximately 50% of newly diagnosed patients are not considered candidates for stem cell transplantation either due to advanced age, poor performance status, or associated comorbidities. Initial therapy consists of either bortezomib/lenalidomide/dexamethasone (VRd) for approximately 9 months followed by lenalidomide maintenance, or daratumumab/lenalidomide/dexamethasone (DRd) given until disease progression. Ixazomib/lenalidomide/dexamethasone is used occasionally for high-risk patients who are unable to access parenteral therapy.[A9] Bortezomib/cyclophosphamide/dexamethasone (VCd) can be used as an alternative if lenalidomide is not available or in the setting of severe renal failure.

Treatment of Relapsed Refractory Myeloma

Almost all patients with multiple myeloma eventually relapse. The general goal is to select a regimen that contains more than two drugs that the patient has not received or to which the disease is or has become refractory. The duration of remission in relapsed multiple myeloma decreases with each regimen. All of the active agents discussed here can be used alone and in combination under expert supervision for the treatment of relapsed multiple myeloma.

The approach to therapy at relapse is complex, and a number of factors must be considered, including response to prior therapy, duration of prior remission, aggressiveness of the relapse, and eligibility for stem cell transplantation.[18] In general, if relapse occurs more than 6 months after stopping therapy, reinstitution of the initial chemotherapy regimen is reasonable. If patients have elected to undergo delayed transplant, then autologous transplantation should be considered. Similarly, eligible patients who have had a reasonable response to a prior autologous transplantation (>18 months without maintenance therapy or >36 months with maintenance therapy) may be considered for a second transplantation. In most patients, one of the triplet regimens (see Table 173-5) is used for the treatment of relapse, with each subsequent relapse treated with sequential regimens that contain drugs that are different than the ones used before. Patients with relapsed refractory myeloma should also be considered for clinical trials.

Specific Options for Relapsed Multiple Myeloma

Thalidomide, lenalidomide, and pomalidomide are closely related immunomodulatory drugs that form the backbone of numerous myeloma treatment regimens. Lenalidomide is better tolerated than thalidomide and has proven efficacy in relapsed myeloma. The starting dose of lenalidomide is 25 mg orally on days 1 to 21, every 28 days. Pomalidomide is a newer, more potent analogue of lenalidomide. All three drugs are associated with a risk of deep vein thrombosis, and therefore routine antithrombotic prophylaxis is needed.

Bortezomib, which is a selective proteasome inhibitor, is useful in relapsed multiple myeloma. The usual dose is 1.3 mg/m^2 administered subcutaneously on days 1, 8, 15, and 22 every 28 days. The once-weekly subcutaneous dosing is associated with significantly lower neuropathy than the twice-weekly intravenous schedule. The most common adverse events are gastrointestinal side effects, fatigue, and neuropathy. Newer proteasome inhibitors that have since been found to be effective in myeloma include carfilzomib and ixazomib.[A10,A11]

Both daratumumab and isatuximab (both of which target CD38) as well as elotuzumab (targeting SLAMF7) are monoclonal antibodies that are effective in the treatment of relapsed multiple myeloma.[A12–A14] Daratumumab can be

administered subcutaneously instead of intravenously without loss of efficacy and is better tolerated.[A15] Several triplet regimens using these agents have been developed for use in relapsed multiple myeloma.

Newer options for the treatment of relapsed refractory myeloma are teclistamab (bispecific antibody),[19] idecabtagene vicleucel (ide-cel; chimeric antigen receptor T [CAR-T] cell therapy),[20] and ciltacabtagene autoleucel (cilta-cel, which is another CAR-T product).[A16] These approaches target the B-cell maturation antigen that is almost universally expressed on the surface of plasma cells. The major toxicity with bispecific antibody and CAR-T therapies are cytokine release syndromes and neurologic complications. Venetoclax (a bcl-2 inhibitor) has significant activity against the t(11;14) subtype of myeloma but is not recommended in other cytogenetic types due to an adverse effect on overall survival.[A17] Other less commonly used options for relapsed myeloma include bendamustine and selinexor (exportin-1 inhibitor).[A18] In addition, traditional chemotherapeutic agents such as doxorubicin are also of benefit in selected patients. Promising investigational agents include newer bispecific antibodies (such as elranatamab, cevostamab, and talquetamab)[21] that target specific antigens expressed on myeloma cells.[22]

Role of Radiation Therapy

Palliative radiation in a dose of 20 to 30 Gy should be limited to patients who have multiple myeloma with disabling pain and a well-defined focal process that has not responded to chemotherapy and to patients with spinal cord compression from a plasmacytoma. Analgesics in combination with chemotherapy can usually control the pain (Chapter 26).

Management of Complications

Hypercalcemia

Hypercalcemia, which is present in 15 to 20% of patients at diagnosis, should be suspected in patients who have anorexia, nausea, vomiting, polyuria, polydipsia, constipation, weakness, confusion, or stupor. If hypercalcemia is untreated, renal insufficiency may develop. Hydration, steroids, and bisphosphonates (zoledronic acid or pamidronate) are recommended and will correct hypercalcemia in almost all patients (Chapter 227).

Renal Insufficiency

The most common cause of acute renal failure is light chain cast nephropathy in patients who have excess excretion of monoclonal protein in urine (myeloma kidney). Aggressive treatment of acute renal failure due to light chain cast nephropathy is critical for long-term overall survival. If the patient is not oliguric, intravenous fluids and furosemide are needed to maintain a high urine flow rate (100 mL/hour). Allopurinol (300 mg daily) is necessary if hyperuricemia is present. If the underlying cause is thought to be light chain cast nephropathy based on clinical findings (e.g., serum free light chains >150 mg/dL) or renal biopsy, plasmapheresis is recommended daily for 5 days to reduce the levels of circulating light chains.[23] Hemodialysis is necessary for symptomatic azotemia. The mainstay of therapy is aggressive treatment of myeloma with a combination regimen such as bortezomib/cyclophosphamide/dexamethasone or daratumumab/bortezomib/cyclophosphamide/dexamethasone or bortezomib/thalidomide/dexamethasone under expert oversight.

Infection

Prompt, appropriate therapy for bacterial infections is necessary. Prophylactic antibiotics such as trimethoprim-sulfamethoxazole should be considered in patients taking high-dose corticosteroids.[24] Acyclovir should be given as prophylaxis against herpes zoster in patients receiving bortezomib. Intravenously administered immunoglobulin is reserved for patients with hypogammaglobulinemia and recurrent severe infections. Pneumococcal and influenza immunizations (Chapter 15) should be given to all patients. COVID vaccination (Chapter 337) is recommended for all patients, and booster doses should also be given as needed.

Skeletal Lesions

Patients should be encouraged to be as active as possible but to avoid trauma. Zoledronic acid (4 mg intravenously over at least 15 minutes every 4 weeks) or pamidronate (90 mg infused intravenously over a 4-hour period every 4 weeks) is recommended for all patients with myeloma bone disease. These agents reduce the incidence of bone pain, pathologic fractures, and spinal cord compression and may improve overall survival. After 1 to 2 years the dosing can be reduced to once every 3 months in patients who are stable to minimize the risk of osteonecrosis of the jaw, which is a complication of long-term bisphosphonate therapy. Denosumab is an alternative agent that can be used in patients who are unable to tolerate zoledronic acid or pamidronate. Kyphoplasty is useful in selected patients with vertebral fractures.

Spinal cord compression from an extramedullary plasmacytoma (Chapter 369) should be suspected in patients who have severe back pain, weakness or paresthesia of the lower extremities, or bladder or bowel dysfunction. Initial treatment is with dexamethasone-based therapy and/or radiation therapy. If the neurologic deficit increases, surgical decompression is necessary.

Miscellaneous Complications

Symptomatic hyperviscosity (see later) is less common than in Waldenström macroglobulinemia. Anemia that persists despite adequate treatment of underlying myeloma often responds to erythropoietin (Chapter 144).

PROGNOSIS

Multiple myeloma is considered incurable at present, but survival has improved significantly in recent years. The median survival is approximately 6 to 7 years in patients who are older than age 65 years, and approximately 12 years in patients who are less than age 65 years and who are eligible for stem cell transplantation, but it varies widely according to clinical stage and risk stratification factors (Table 173-4). In some patients, an acute or aggressive terminal phase is characterized by rapid tumor growth, pancytopenia, soft tissue subcutaneous masses, decreased M protein levels, and fever; survival in this subset is generally limited to a few months.

VARIANT FORMS OF MULTIPLE MYELOMA

PLASMA CELL LEUKEMIA

Patients who have multiple myeloma with more than 5% plasma cells in the peripheral blood differential count and/or an absolute plasma cell count of 500/μL or greater are considered to have plasma cell leukemia.[25] Plasma cell leukemia is classified as primary when it is diagnosed in the leukemic phase (60%) or as secondary when there is leukemic transformation of a previously recognized multiple myeloma (40%). Patients with primary plasma cell leukemia are younger and have a greater incidence of hepatosplenomegaly and lymphadenopathy, a higher platelet count, fewer bone lesions, a smaller serum M protein component, and better survival than do patients with secondary plasma cell leukemia.

TREATMENT AND PROGNOSIS

Current treatments are generally unsatisfactory. An aggressive initial treatment regimen under expert supervision is a reasonable strategy. Options include bortezomib/dexamethasone/thalidomide/cisplatin/doxorubicin/cyclophosphamide/etoposide (VDT-PACE) or daratumumab plus bortezomib/lenalidomide/dexamethasone, followed by autologous stem cell transplantation and subsequent maintenance therapy with bortezomib plus lenalidomide. Nonetheless, the prognosis of primary plasma cell leukemia is significantly worse than high-risk multiple myeloma.

NONSECRETORY MYELOMA

Patients with nonsecretory myeloma have no M protein in either serum or urine and account for only 3% of cases of myeloma. To establish the diagnosis, the clonal nature of bone marrow plasma cells should be confirmed by immunoperoxidase, immunofluorescence, or flow cytometric methods. Treatment and survival are similar to those in patients with typical myeloma. The serum free light chain assay is abnormal in more than 60% of patients and can be used to monitor the response to therapy.

OSTEOSCLEROTIC MYELOMA (POEMS SYNDROME)

Osteosclerotic myeloma is characterized by polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes (POEMS).[26] Almost all patients have a λ-type M protein. The major clinical features are a chronic inflammatory-demyelinating polyneuropathy with predominantly motor disability and sclerotic skeletal lesions. The bone marrow usually contains less than 5% plasma cells, and hypercalcemia and renal insufficiency rarely occur. The diagnosis is confirmed by identification of monoclonal plasma cells obtained at biopsy of an osteosclerotic lesion.

If the lesions are in a limited area, radiation therapy substantially improves the neuropathy in more than 50% of patients. If the patient has widespread osteosclerotic lesions, treatment is with autologous stem cell transplantation or other systemic therapy similar to that used for myeloma.[27]

SOLITARY PLASMACYTOMA (SOLITARY MYELOMA) OF BONE

The diagnosis of solitary bone plasmacytoma is based on histologic evidence of a solitary tumor consisting of monoclonal plasma cells identical to those in multiple myeloma. In addition, PET-CT (or whole body CT) or MRI of the spine and pelvis must show no other lesions of myeloma, and the bone marrow aspirate must contain no evidence of clonal plasma cells. An M protein may be present in serum or urine at diagnosis, but persistence of the M protein after radiation therapy is associated with an increased risk for progression to

multiple myeloma. Treatment consists of radiation in the range of 40 to 50 Gy. Patients with an apparent solitary plasmacytoma who have limited (<10%) clonal marrow involvement are considered to have solitary plasmacytoma with minimal marrow involvement (Table 173-2). The risk of recurrence or progression to multiple myeloma within 3 years is approximately 10% in patients with solitary plasmacytoma versus 60% in patients with solitary plasmacytoma and minimal marrow involvement.

EXTRAMEDULLARY PLASMACYTOMA

Extramedullary plasmacytomas outside the bone marrow are most commonly found in the upper respiratory tract (80% of cases), especially in the nasal cavity and sinuses, nasopharynx, and larynx. Extramedullary plasmacytomas may also occur in the gastrointestinal tract, central nervous system, urinary bladder, thyroid, breast, testes, parotid gland, or lymph nodes. Extramedullary plasmacytomas may be solitary,[28] or they may occur in the context of existing myeloma. The diagnosis of solitary extramedullary plasmacytoma is based on detection of a plasma cell tumor in an extramedullary site, absence of clonal plasma cells on bone marrow examination, and absence of other bony or extramedullary lesions on radiographic studies. Treatment of solitary extramedullary plasmacytoma consists of either complete surgical resection or tumoricidal irradiation. The plasmacytoma may recur locally, metastasize to regional nodes, or, rarely, develop into multiple myeloma. Prognosis is generally better in patients with solitary extramedullary plasmacytoma, compared with solitary bony plasmacytoma.

WALDENSTRÖM MACROGLOBULINEMIA (PRIMARY MACROGLOBULINEMIA)

Waldenström macroglobulinemia is the result of the uncontrolled proliferation of lymphocytes and plasma cells in which an IgM M protein is produced. The median age of patients at the time of diagnosis is about 65 years, and approximately 60% are male. The cause is unknown, but familial clusters have been reported. A recurrent mutation of the *MYD88* gene (*MYD88 L265P*) is present in most patients with Waldenström macroglobulinemia and is thought to be relatively specific for this disease.

CLINICAL MANIFESTATIONS

Weakness, fatigue, and bleeding (especially oozing from the oronasal area) are common initial symptoms. Blurred or impaired vision, dyspnea, weight loss, neurologic symptoms, recurrent infections, and heart failure may occur. In contrast to multiple myeloma, lytic bone lesions, renal insufficiency, and amyloidosis are rare. Physical findings include pallor, hepatosplenomegaly, and lymphadenopathy. Retinal hemorrhages, exudates, and venous congestion with vascular segmentation ("sausage" formation) may occur. Sensorimotor peripheral neuropathy is common. Pulmonary involvement is manifested by diffuse pulmonary infiltrates and isolated masses.

Laboratory Evaluation

Almost all patients have moderate to severe normocytic, normochromic anemia. The serum electrophoretic pattern is characterized by a tall, narrow peak or dense band that is of the IgM type on immunofixation. Quantitative IgM levels are high. A monoclonal light chain is detected in the urine of 80% of patients, but the amount of urinary protein is generally modest.

The bone marrow aspirate is often hypocellular, but the biopsy is hypercellular and extensively infiltrated with lymphoid cells and plasma cells or lymphoplasmacytic cells. The number of mast cells is frequently increased. Rouleaux formation is prominent (Chapter 143), and the sedimentation rate is markedly increased. About 10% of cases may have an associated type I cryoglobulinemia (see later).

DIAGNOSIS

Diagnosis requires the combination of typical symptoms and physical findings, the presence of an IgM M protein, and 10% or greater lymphoplasmacytic infiltration of the bone marrow.[29]

Diagnostic Criteria and Differential Diagnosis

The diagnostic criteria are IgM monoclonal gammopathy (regardless of the size of the M protein), 10% or greater bone marrow infiltration (usually intertrabecular) by clonal lymphocytes that exhibit plasmacytoid or plasma cell differentiation, and a typical immunophenotype (e.g., surface IgM$^+$, CD5$^{+/-}$, CD10$^-$, CD19$^+$, CD20$^+$, CD23$^-$) that would satisfactorily exclude other lymphoproliferative disorders, including CLL (Chapter 169) and mantle cell lymphoma (Chapter 171).

Patients who meet the diagnostic criteria for Waldenström macroglobulinemia but who have less than 3 g/dL IgM protein at diagnosis have sometimes been classified as having "lymphoplasmacytic lymphoma with an IgM M protein" (Chapter 171). However, except for hyperviscosity, the clinical picture, therapy, and prognosis for these patients do not differ from those of patients with an IgM level of 3 g/dL or greater; thus, these patients are also considered to have Waldenström macroglobulinemia by the current definition.

Asymptomatic patients with 10% or greater lymphoplasmacytic infiltration of the bone marrow are considered to have smoldering Waldenström macroglobulinemia. Multiple myeloma, CLL, and MGUS of the IgM type must be excluded.

TREATMENT AND PROGNOSIS

Patients should not be treated unless they have anemia; constitutional symptoms such as weakness, fatigue, night sweats, or weight loss; hyperviscosity; or significant hepatosplenomegaly or lymphadenopathy. The most common regimens used as front-line therapy are the combination of ibrutinib plus rituximab,[A19] bendamustine plus rituximab, or dexamethasone/rituximab/cyclophosphamide.[30]

For relapse, the agents used as initial therapy can be given alone or in combination. Zanubrutinib, which is a more selective Bruton tyrosine kinase inhibitor, has comparable activity to ibrutinib and may be better tolerated.[A20] Autologous stem cell transplantation can be considered for eligible patients with relapsed disease. Other options under expert supervision include venetoclax, cladribine, or fludarabine (with or without rituximab); lenalidomide-based or bortezomib-based regimens; and other regimens used in the treatment of non-Hodgkin lymphoma (Chapter 171).

Spuriously low hemoglobin and hematocrit levels may occur because of the increased plasma volume from the large amount of intravascular M protein. Symptomatic hyperviscosity should be treated by plasmapheresis. The median survival of patients with macroglobulinemia is in excess of 5 to 7 years.

HYPERVISCOSITY SYNDROME

Hyperviscosity syndrome occurs when patients with Waldenström macroglobulinemia have high levels of serum IgM M protein (>5 g/dL) and occasionally in those with myeloma, especially of the IgA type. For any given level of paraprotein, IgM or IgA is more likely than IgG to cause hyperviscosity because the former circulate as pentamers or dimers, respectively, in contrast to monomeric IgG. Chronic nasal bleeding and oozing from the gums are the most frequent symptoms of hyperviscosity, but postsurgical or gastrointestinal bleeding may also occur. Retinal hemorrhages are common, and venous congestion with sausage-like segmentation and papilledema may be seen (Fig. 173-9). The patient occasionally complains of blurring or loss of vision. Dizziness, headache, vertigo, nystagmus, decreased hearing, ataxia, paresthesias, diplopia, somnolence, and coma may occur. Hyperviscosity can precipitate or exacerbate heart failure. Most patients have symptoms when the relative viscosity is greater than 4 cP, but the relationship between serum viscosity and clinical manifestations is not precise.

TREATMENT

Patients with symptomatic hyperviscosity should be treated with plasmapheresis and with chemotherapy to treat the underlying malignancy. Plasma exchange of 3 to 4 L with albumin should be performed daily until the patient is asymptomatic. Plasma exchange is rapidly effective (two to three exchanges) for IgM M proteins, which are primarily intravascular. For IgG M proteins, however, multiple attempts may be needed because a significant amount of IgG can exist in the extravascular space.

HEAVY CHAIN DISEASES

The heavy chain diseases are characterized by the presence of an M protein consisting of a portion of the immunoglobulin heavy chain in serum, urine, or both. These heavy chains are devoid of light chains and represent a lymphoplasma cell proliferative process. The three major types are γ-heavy chain disease, α-heavy chain disease, and μ-heavy chain disease.

γ-HEAVY CHAIN DISEASE

Patients with γ-heavy chain disease often initially have a lymphoma-like illness, but the clinical findings are diverse and range from an aggressive

FIGURE 173-9. Hyperviscosity syndrome. Right eye retinal image in a patient with Waldenström macroglobulinemia and hyperviscosity syndrome showing sausaging (focal venular dilations), intraretinal hemorrhages, microaneurysms, and peripapillary cotton-wool spots and disc swelling (papilledema).

lymphoproliferative process to an asymptomatic state. Hepatosplenomegaly and lymphadenopathy occur in about 60% of patients. Anemia is found in approximately 80% initially and in nearly all eventually. The electrophoretic pattern often shows a broad-based band more suggestive of a polyclonal increase than an M protein. The diagnosis depends on the identification of an isolated monoclonal γ-heavy chain on serum immunofixation, without evidence of either monoclonal κ or λ light chain expression.

TREATMENT AND PROGNOSIS

Treatment is indicated only for symptomatic patients and consists of chemotherapy with regimens used to treat non-Hodgkin lymphoma (Chapter 171), such as cyclophosphamide, vincristine, and prednisone. The prognosis of γ-heavy chain disease is variable and ranges from a rapidly progressive downhill course of a few weeks' duration to the asymptomatic presence of a stable monoclonal heavy chain in serum or urine.

α-HEAVY CHAIN DISEASE

α-Heavy chain disease, which is the most common form of heavy chain disease, occurs in patients from the Mediterranean region or the Middle East, generally in the second or third decade of life. About 60% of patients with α-heavy chain disease are men. Most commonly the gastrointestinal tract is involved, and severe malabsorption with diarrhea, steatorrhea, and weight loss is noted (Chapter 126). Plasma cell infiltration of the jejunal mucosa is the most frequent pathologic feature. Immunoproliferative small intestinal disease is restricted to patients with small intestinal lesions who have the pathologic features of α-heavy chain disease but do not synthesize α-heavy chains.

The serum protein electrophoretic pattern is normal in about 50% of cases. In the remainder, an unimpressive broad band may appear in the α_2 or β region. The diagnosis depends on identification of an isolated monoclonal α-heavy chain on serum immunofixation, without evidence of either monoclonal κ or λ light chain expression. The amount of α-heavy chain in urine is small.

TREATMENT AND PROGNOSIS

In the absence of therapy, α-heavy chain disease is typically progressive and fatal. The usual treatment consists of antibiotics, such as tetracyclines, and the eradication of any concurrent parasitic infection. Patients who do not respond adequately to antibiotics are given chemotherapy similar to that used to treat non-Hodgkin lymphoma, for example, the cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone (CHOP) regimen (Chapter 171).

FIGURE 173-10. Skin infarction in cryoglobulinemia. The skin has a reticulated pattern as a result of leakage of red blood cells from damaged skin capillaries. Necrosis and ulceration have occurred in peripheral sites because of vessel blockage. This patient eventually required plastic surgery. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

μ-HEAVY CHAIN DISEASE

μ-Heavy chain disease disease is characterized by the demonstration of an isolated monoclonal μ-chain fragment on serum immunofixation, without evidence of either monoclonal κ or λ light chain expression. The serum protein electrophoretic pattern is usually normal, except for hypogammaglobulinemia. Bence Jones proteinuria is found in two thirds of cases. Lymphocytes, plasma cells, and lymphoplasmacytoid cells are increased in the bone marrow. Vacuolization of the plasma cells is common and should suggest the possibility of heavy chain disease.

TREATMENT AND PROGNOSIS

Treatment is with corticosteroids and alkylating agents. The course of μ-heavy chain disease is variable, and survival ranges from a few months to many years.

CRYOGLOBULINEMIA

Cryoglobulins are plasma proteins that precipitate when cooled and dissolve when heated. They are designated as idiopathic or essential when they are not associated with any recognizable disease. Cryoglobulins are classified into three types: type I (monoclonal), type II (mixed monoclonal plus polyclonal), and type III (polyclonal).[31]

TYPE I CRYOGLOBULINEMIA

Type I (monoclonal) cryoglobulinemia is most commonly of the IgM or IgG class, but IgA and Bence Jones cryoglobulins have been reported. Most patients, even with large amounts of type I cryoglobulin, are completely asymptomatic from this source. Others with monoclonal cryoglobulins in the range of 1 to 2 g/dL may have evidence of vasculitis with pain, purpura, Raynaud phenomenon, cyanosis, and even ulceration and sloughing of skin and subcutaneous tissue (Fig. 173-10) on exposure to cold because their cryoglobulins precipitate at relatively high temperatures. Type I cryoglobulins are associated with macroglobulinemia, multiple myeloma, or MGUS.

TREATMENT

Therapy for patients with symptomatic type I cryoglobulinemia and significant symptoms is similar to that for Waldenström macroglobulinemia for the IgM type and multiple myeloma for the non-IgM type.

TYPE II CRYOGLOBULINEMIA

Type II (mixed) cryoglobulinemia typically consists of an immune complex of IgM M protein and polyclonal IgG, although monoclonal IgG or monoclonal IgA may also be seen with polyclonal IgM. Serum protein electrophoresis generally shows a normal pattern or a diffuse, polyclonal hypergammaglobulinemic pattern. The quantity of mixed cryoglobulin is usually less than 0.2 g/dL. Despite the monoclonal component, most patients do not have a clonal plasma cell disorder; rather, they have serologic evidence of infection with

hepatitis C virus (Chapter 135). At present, hepatitis C is thought to be the cause of most cases of type II cryoglobulinemia.

Most clinical manifestations are related to the development of vasculitis and include palpable purpura, livedo reticularis, polyarthralgias, and neuropathy. Involvement of the joints is symmetrical, but joint deformities rarely develop. Raynaud phenomenon, necrosis of the skin, and neurologic involvement may be present. In almost 80% of renal biopsy specimens, glomerular damage can be identified. Nephrotic syndrome may result, but severe renal insufficiency is uncommon.

TREATMENT

Treatment should target the underlying hepatitis C infection (Chapter 135). Administration of corticosteroids is often needed to control vasculitis. Agents to treat the monoclonal component, such as cyclophosphamide or rituximab, are used if there is no response. Plasmapheresis (with a warmed circuit) is helpful in the acute management of symptoms by removing circulating immune complexes.

TYPE III CRYOGLOBULINEMIA

Type III (polyclonal) cryoglobulinemia does not have a monoclonal component and is not associated with a clonal plasma cell proliferative disorder. Type III cryoglobulins are found in many patients with chronic infections or inflammatory diseases and are usually of no clinical significance unless associated with hepatitis C infection.

174 AMYLOIDOSIS

MORIE A. GERTZ AND ANGELA DISPENZIERI

The amyloidoses are protein-misfolding diseases caused by a precursor protein that undergoes a conformational change, which in turn triggers the formation of amyloid fibrils that damage different organs. Amyloidosis can be either localized or systemic. In systemic amyloidosis (Table 174-1), amyloid deposition occurs at sites distant from where the precursor protein is formed.[1] In localized amyloidosis, the deposits form exclusively where the precursor protein is synthesized. Despite differences in structure and function, amyloid fibrils formed by all these various precursor proteins share a cross-β structure and form 2- to 5-nm-diameter filaments that either coil together or form laterally adherent fibrils with distinct intensities at 4.7 and 10 angstroms.

SYSTEMIC AMYLOIDOSIS

EPIDEMIOLOGY

The incidence of AL (formerly called primary) amyloidosis is about 12 per million persons per year. In one large series confirmed by mass spectroscopy, about 60% of cases were immunoglobulin amyloidosis, about 30% were transthyretin or TTR amyloidosis, and only about 3% were secondary amyloidosis. Familial amyloidosis mostly involves mutated transthyretin but also includes other rare mutations (Table 174-1). Wild-type TTR amyloidosis is often clinically unrecognized and is much more common than originally believed.

SYSTEMIC LIGHT CHAIN AMYLOIDOSIS

PATHOBIOLOGY

In rare cases, light chain amyloidosis can be familial, owing to a mutation in the light chain gene, rather than caused by a monoclonal plasma cell dyscrasia. Immunoglobulin light chain amyloidosis is characterized by a clonal population of bone marrow plasma cells that produces a monoclonal light chain of the κ or λ type, as either an intact molecule or a fragment. The light chain protein, instead of conforming to the α-helical configuration of most proteins, misfolds and forms a β-pleated sheet.[2] This insoluble protein is deposited in tissues and interferes with organ function. The β-pleated sheet configuration is responsible for the tinctorial properties; when the protein is stained with Congo red and viewed under polarized light, apple-green birefringence is demonstrated and is required for the diagnosis.

CLINICAL MANIFESTATIONS

The presenting symptoms can be diverse and are mimicked by far more common disorders (Table 174-2). The signs include tongue enlargement with dental indentations (Fig. 174-1) and "pinch" or periorbital purpura (Fig. 174-2), which is a result of vascular fragility. The signs are specific but lack sensitivity in that they are present in no more than 15% of patients.

Renal Involvement

The kidney is commonly involved in AL amyloidosis (58% of cases). The diagnosis should be suspected in any patient who presents with nondiabetic nephrotic-range proteinuria (Chapter 100).[3] One third of patients with AL amyloidosis have nephrotic syndrome that is manifested with dramatic increases in the blood cholesterol level (median, 270 mg/dL), and urinalysis for proteinuria should be done in patients with a sudden increase in the serum cholesterol

hepatitis C virus (Chapter 135). At present, hepatitis C is thought to be the cause of most cases of type II cryoglobulinemia.

Most clinical manifestations are related to the development of vasculitis and include palpable purpura, livedo reticularis, polyarthralgias, and neuropathy. Involvement of the joints is symmetrical, but joint deformities rarely develop. Raynaud phenomenon, necrosis of the skin, and neurologic involvement may be present. In almost 80% of renal biopsy specimens, glomerular damage can be identified. Nephrotic syndrome may result, but severe renal insufficiency is uncommon.

TREATMENT

Treatment should target the underlying hepatitis C infection (Chapter 135). Administration of corticosteroids is often needed to control vasculitis. Agents to treat the monoclonal component, such as cyclophosphamide or rituximab, are used if there is no response. Plasmapheresis (with a warmed circuit) is helpful in the acute management of symptoms by removing circulating immune complexes.

TYPE III CRYOGLOBULINEMIA

Type III (polyclonal) cryoglobulinemia does not have a monoclonal component and is not associated with a clonal plasma cell proliferative disorder. Type III cryoglobulins are found in many patients with chronic infections or inflammatory diseases and are usually of no clinical significance unless associated with hepatitis C infection.

174 AMYLOIDOSIS

MORIE A. GERTZ AND ANGELA DISPENZIERI

The amyloidoses are protein-misfolding diseases caused by a precursor protein that undergoes a conformational change, which in turn triggers the formation of amyloid fibrils that damage different organs. Amyloidosis can be either localized or systemic. In systemic amyloidosis (Table 174-1), amyloid deposition occurs at sites distant from where the precursor protein is formed.[1] In localized amyloidosis, the deposits form exclusively where the precursor protein is synthesized. Despite differences in structure and function, amyloid fibrils formed by all these various precursor proteins share a cross-β structure and form 2- to 5-nm-diameter filaments that either coil together or form laterally adherent fibrils with distinct intensities at 4.7 and 10 angstroms.

SYSTEMIC AMYLOIDOSIS

EPIDEMIOLOGY

The incidence of AL (formerly called primary) amyloidosis is about 12 per million persons per year. In one large series confirmed by mass spectroscopy, about 60% of cases were immunoglobulin amyloidosis, about 30% were transthyretin or TTR amyloidosis, and only about 3% were secondary amyloidosis. Familial amyloidosis mostly involves mutated transthyretin but also includes other rare mutations (Table 174-1). Wild-type TTR amyloidosis is often clinically unrecognized and is much more common than originally believed.

SYSTEMIC LIGHT CHAIN AMYLOIDOSIS

PATHOBIOLOGY

In rare cases, light chain amyloidosis can be familial, owing to a mutation in the light chain gene, rather than caused by a monoclonal plasma cell dyscrasia. Immunoglobulin light chain amyloidosis is characterized by a clonal population of bone marrow plasma cells that produces a monoclonal light chain of the κ or λ type, as either an intact molecule or a fragment. The light chain protein, instead of conforming to the α-helical configuration of most proteins, misfolds and forms a β-pleated sheet.[2] This insoluble protein is deposited in tissues and interferes with organ function. The β-pleated sheet configuration is responsible for the tinctorial properties; when the protein is stained with Congo red and viewed under polarized light, apple-green birefringence is demonstrated and is required for the diagnosis.

CLINICAL MANIFESTATIONS

The presenting symptoms can be diverse and are mimicked by far more common disorders (Table 174-2). The signs include tongue enlargement with dental indentations (Fig. 174-1) and "pinch" or periorbital purpura (Fig. 174-2), which is a result of vascular fragility. The signs are specific but lack sensitivity in that they are present in no more than 15% of patients.

Renal Involvement

The kidney is commonly involved in AL amyloidosis (58% of cases). The diagnosis should be suspected in any patient who presents with nondiabetic nephrotic-range proteinuria (Chapter 100).[3] One third of patients with AL amyloidosis have nephrotic syndrome that is manifested with dramatic increases in the blood cholesterol level (median, 270 mg/dL), and urinalysis for proteinuria should be done in patients with a sudden increase in the serum cholesterol

ABSTRACT

The amyloidoses are protein-misfolding diseases caused by a precursor protein that undergoes a conformational change, which in turn triggers the formation of amyloid fibrils that damage different organs. Amyloidosis can be either localized or systemic. The systemic amyloidoses can be manifested clinically in many organs, most notably the heart, kidneys, liver, peripheral nerves, skin, gastrointestinal tract, and the microvasculature of the brain. Diagnosis can be confirmed by mass spectrometry or immunoelectron microscopy (for unequivocal amyloid typing) of a Congo red–positive tissue biopsy of clinically involved organs or surrogate tissue, such as subcutaneous fat pad or bone marrow. The amyloidoses are not common and their presenting symptoms may be missed or confused with other clinical entities. For light chain amyloidosis, current therapy produces response rates of about 70% and median survival upward of 5 years.

KEYWORDS

amyloidosis
light chain
monoclonal immunoglobulin
nephrotic syndrome
restrictive cardiomyopathy
stem cell transplant

TABLE 174-1 SYSTEMIC AMYLOIDOSES

DISEASE	CAUSE	AFFECTED ORGANS
AL (Light chain) amyloidosis (formerly primary amyloidosis)	Immunoglobulin light chain	Heart, kidney, liver, nerve
AL (Heavy chain) amyloidosis	Immunoglobulin heavy chain	Kidney, liver, heart
TTRwt (formerly senile cardiac) amyloidosis	Accumulation of wild-type transthyretin	Heart, vessels, soft tissues (especially ligaments)
TTRm (formerly familial) amyloidosis	Hereditary mutation of transthyretin	Heart, kidney, peripheral nervous system
ALECT2	No mutation etiology not known	Kidney, liver
AA (Secondary) amyloidosis	Overproduction of serum amyloid A protein because of chronic inflammation	Kidney, liver, spleen
AB2 M wild-type (dialysis-related) amyloidosis	Acquired copper-triggered oligomerization of β_2-microglobulin	Musculoskeletal system
AB2 M variant amyloidosis	Hereditary variant of β_2-microglobulin	Autonomic nervous system
ALYS	Hereditary mutation of lysozyme	Kidney, liver, spleen
ApoAI amyloidosis	Hereditary mutation of apolipoprotein AI	Kidney, heart, liver
ApoAII amyloidosis	Hereditary mutation of apolipoprotein AII	Kidney
ApoAIV amyloidosis	Hereditary mutation of apolipoprotein AIV	Kidney
ApoCII amyloidosis	Hereditary mutation of apolipoprotein C II	Kidney
ApoCIII amyloidosis	Hereditary mutation of apolipoprotein C III	Kidney
AFib amyloidosis	Hereditary mutation of fibrinogen α chain	Kidney
AGel (Finnish hereditary) amyloidosis	Hereditary mutation of gelsolin	Cornea, facial and peripheral nerves, skin
ACys amyloidosis	Hereditary mutation of cystatin C	Peripheral nervous system, skin
ABri amyloidosis	Hereditary mutation of BriPP	Microvasculature of the brain

Apo = apolipoprotein; BriPP = Bri precursor protein; wtTTR = wild-type transthyretin.

TABLE 174-2 SYMPTOMS, SIGNS, AND SYNDROMES OF SYSTEMIC AMYLOIDOSIS

SYMPTOMS AND SIGNS
Common symptoms: fatigue, edema, dyspnea, anorexia, paresthesias Rare symptoms: claudication, joint pain and stiffness, sicca syndrome Common signs: periorbital purpura, glossomegaly, hepatomegaly Rare signs: waxy infiltration of eyelids, shoulder pad sign
SYNDROMES
Nondiabetic nephrotic syndrome Nonischemic cardiomyopathy with an echocardiogram showing "hypertrophy" Hepatomegaly or increased alkaline phosphatase with no imaging abnormality Peripheral neuropathy with monoclonal gammopathy of undetermined significance or chronic inflammatory demyelinating polyneuropathy with autonomic features Atypical monoclonal gammopathy of undetermined significance or myeloma with monoclonal light chains and modest marrow plasmacytosis

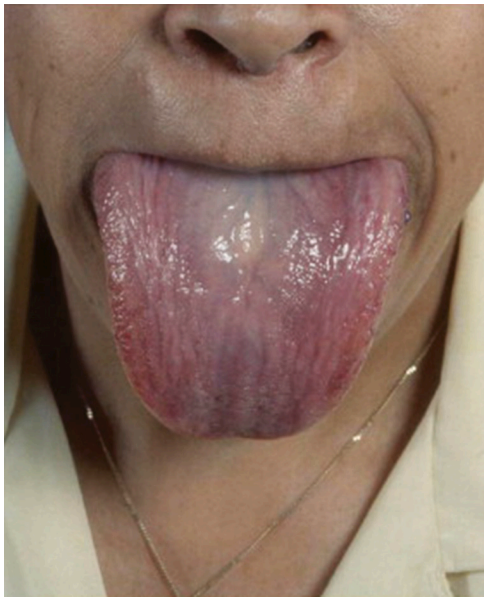

FIGURE 174-1. Macroglossia (or glossomegaly) in a patient with amyloidosis. (From Esplin BL, Gertz MA. Current trends in diagnosis and management of cardiac amyloidosis. *Curr Probl Cardiol*. 2013;38:53-96.)

FIGURE 174-2. Periorbital purpura in amyloidosis. (From Kitchens CS. Purpura and other hematovascular disorders. In: Kitchens CS, Konkle BA, Kessler CM, eds. *Consultative Hemostasis and Thrombosis*. 3rd ed. Philadelphia: Elsevier; 2012.)

level. Ten percent of renal biopsy specimens from patients with nondiabetic nephrotic syndrome are subsequently shown to be involved by amyloidosis. The incidence of bleeding after percutaneous renal biopsy is not increased in patients with AL amyloidosis.

Cardiac Involvement

The heart is involved in approximately 70% of patients with AL amyloidosis, and the presentation of disease is subtle because fatigue is often the only manifestation.[4] Because amyloid heart disease (Chapter 47) is a disorder of diastolic failure, the typical findings of cardiomyopathy (enlarged cardiac silhouette, depressed ejection fraction, and pulmonary vascular redistribution) are absent. The effect of amyloidosis on the heart is poor filling during diastole. Patients have low end-diastolic volume and, as a consequence, poor stroke volume, despite a completely normal ejection fraction.[5] Cardiac conduction abnormalities (Chapter 51) are common and can be a presenting clinical manifestation. Patients with amyloidosis rarely have symptoms of ischemic heart disease. Imaging is typically not helpful, and liver uptake is homogeneous. Liver biopsy is not associated with an increased rate of bleeding.

Neuropathy

The peripheral neuropathy (Chapter 388) associated with AL amyloidosis (seen in approximately 15% of patients) begins in the lower extremities, is symmetrical, and is generally sensory or mixed sensorimotor. When a monoclonal protein is recognized, frequent diagnoses are chronic inflammatory demyelinating polyneuropathy and neuropathy associated with monoclonal gammopathy of undetermined significance. Associated autonomic neuropathy occurs in approximately 4% of patients and can be characterized by orthostatic hypotension, which may be misattributed to cardiac failure.

Carpal tunnel syndrome (Chapter 384) occurs in approximately 10 to 15% of patients. It is not clinically distinguishable from the syndrome associated with repetitive stress injury but may fail to improve after surgical release.

Gastrointestinal/Liver

Autonomic dysmotility of the bowel is a common associated finding (Chapter 122). It can be upper intestinal, leading to pseudo-obstruction and recurrent emesis, or lower intestinal, characterized by alternating obstipation and fecal incontinence. Diarrhea caused by autonomic failure can be misdiagnosed as collagenous colitis when eosinophilic deposits are found in the bowel mucosa on hematoxylin-eosin staining in the absence of Congo red staining.

The liver is involved in 10 to 20% of patients with AL amyloidosis, and the typical presentation is hepatomegaly with an increased serum alkaline phosphatase value. Increased aminotransferase levels and hyperbilirubinemia are generally late signs. Many patients undergo evaluation for suspected malignant disease due to liver enlargement.

Other Symptoms

Rarely, patients present with spontaneous splenic rupture. Acquired deficiency of coagulation factor X (Chapter 160) is specific to AL amyloidosis and can be associated with severe hemorrhage. Interstitial lung disease, pseudoclaudication, periarticular deposits, and unexplained weight loss rarely are presenting symptoms.

DIAGNOSIS

AL amyloidosis is particularly difficult to diagnose. No single imaging procedure or laboratory study is diagnostic for AL amyloidosis. The clinician must therefore be aware of the possibility of amyloidosis, or it may be overlooked.[6]

In a patient with nondiabetic proteinuria, cardiomyopathy without ischemic risk factors, unexplained hepatomegaly, peripheral or autonomic neuropathy, or carpal tunnel syndrome, amyloidosis is not the most likely cause. The classic physical finding of periorbital purpura occurs in only 10% of patients, is often limited to petechial eruptions over the eyelids, and is easily overlooked. Enlargement of the tongue occurs in 10 to 15% of patients; therefore, although it is specific, it is not sensitive for the diagnosis. AL amyloidosis in patients with an enlarged tongue may be unrecognized, or these patients may be evaluated for acromegaly or undergo unnecessary tongue biopsies because of the suspicion of squamous cell cancer.

Initial Testing

When a patient presents with a compatible clinical syndrome, immunofixation of serum and a urine-free light chain assay should be completed before invasive diagnostic studies are performed (Fig. 174-3). Simple electrophoresis without immunofixation is inadequate because the monoclonal proteins are quantitatively very small in most patients and will not cause a detectable peak on serum protein electrophoresis. When these three diagnostic studies are used in combination, the sensitivity is 100%. The existence of a monoclonal protein, however, is not sufficiently specific to establish the diagnosis of AL amyloidosis.

With modern testing, a monoclonal component can be found in approximately 25% of patients with ATTRwt amyloidosis, so typing of the amyloid tissue is critical. If a monoclonal protein is not found, three possibilities exist: (1) the patient does not have amyloidosis; (2) if the patient is known to have amyloidosis, it may be localized rather than systemic; or (3) if the patient is known to have systemic amyloidosis, it may be ATTRwt (senile systemic) or ATTRm (familial type) rather than the light chain type (see later section on other forms of amyloidosis).

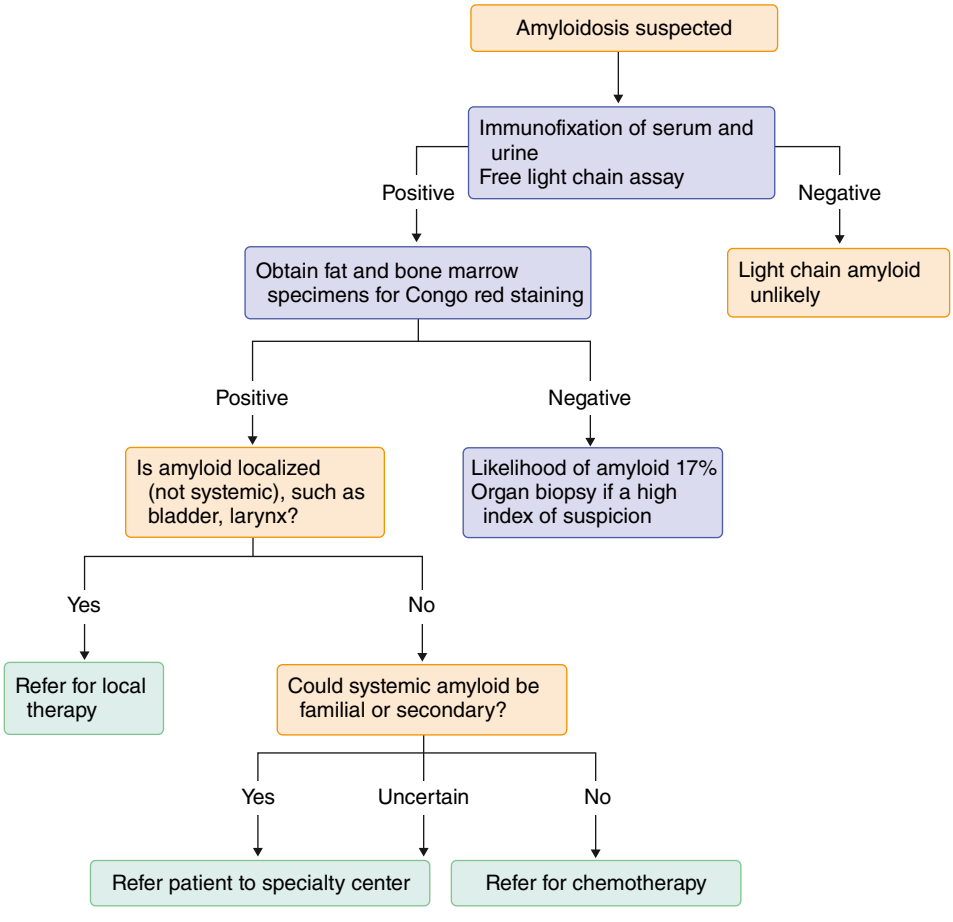

FIGURE 174-3. Algorithm for the cost-effective pursuit of a diagnosis of systemic light chain amyloidosis.

Differential Diagnosis

Systemic AL amyloidosis can be confused with early multiple myeloma (Chapter 174). Patients who present with vague symptoms of fatigue and edema are found to have a monoclonal protein in the urine, and a bone marrow biopsy specimen shows a clonal plasmacytosis with a median of 10% plasma cells in the bone marrow. These patients are often considered to have atypical multiple myeloma when the underlying amyloid syndrome is unrecognized. Taken together, a misdiagnosis of myeloma kidney or demyelinating neuropathy is made when an adequate diagnostic evaluation to exclude amyloidosis has not been performed.

Systemic AL amyloidosis also must be distinguished from systemic amyloidosis associated with inherited amyloid cardiomyopathies and neuropathies (familial amyloidoses) or cardiac amyloidosis caused by deposition of aberrant transthyretin. By definition, AL amyloidosis is a plasma cell dyscrasia (Chapter 174); therefore, virtually all patients have a detectable immunoglobulin abnormality by immunofixation of the serum or urine, or they have abnormal results on a serum immunoglobulin free light chain assay.

Definitive Testing

In view of the grave prognosis associated with AL amyloidosis, the diagnosis must be confirmed by biopsy (with Congo red staining) in all cases.[7] Subcutaneous fat aspiration is an outpatient procedure that has a 24-hour turnaround time, recognizes amyloid deposits in 70% of patients, and is the initial diagnostic test that should be performed to confirm AL amyloidosis. Bone marrow is a second convenient biopsy site, and this test is often required to exclude the possibility of associated multiple myeloma. Bone marrow biopsy is positive in 50% of patients. When both subcutaneous fat aspiration and bone marrow biopsy are combined, amyloid is detected in approximately 80% of patients. The remaining patients should have biopsy of the appropriate involved organ: the kidney when proteinuria is the presenting symptom, the heart when cardiomyopathy is recognized, the liver in patients who have hepatomegaly and an increased alkaline phosphatase value, or the nerve if sensorimotor functional loss is present. These latter procedures are quite invasive and often are not required for definitive diagnosis of AL amyloidosis.

Once amyloid deposits are detected in tissues, further diagnostic evaluation is required (Fig. 174-3). The presence of a monoclonal protein in the serum or urine and the presence of congophilic deposits in tissue do not verify that amyloidosis is light chain in origin. Further diagnostic studies are essential to classify the type of amyloid before therapy is initiated. Immunohistochemical studies on the tissue may be useful, but misfolding of the amyloid light chain often prevents epitopes from being recognized by commercial antisera; as a result, false-negative and false-positive results are common. Mass spectrometric analysis of the amyloid deposit can be performed on paraffin-embedded tissue and validates the type of amyloid by direct amino acid sequencing, thereby leaving no question about the origin of the amyloid protein as an immunoglobulin light chain. Alternatively, immunoelectron microscopy can be used to type the amyloid. Each of these tests have a specificity of nearly 100% for light chain amyloidosis.

When the heart is involved, electrocardiography frequently shows a pseudoinfarct pattern, which can be interpreted as demonstrating silent ischemic infarction; this finding can lead to coronary angiography, which is invariably negative (unless the patient has coincidental coronary artery disease). Echocardiography shows thickening of the heart walls and a hyperreflective granular texture (see Fig. 47-8) due to amyloid infiltration but can be misinterpreted as showing left ventricular hypertrophy. Enhancement on magnetic resonance imaging with gadolinium is delayed in approximately 70% of patients with cardiac amyloidosis. Myocardial enhancement is associated with increased ventricular mass and impaired left ventricular systolic function. Technetium pyrophosphate (Tc^{99} PYP) imaging of the heart can be supportive of a diagnosis of ATTR amyloidosis (see E-Fig. 44-4).

TREATMENT

AL amyloidosis was previously thought to be untreatable and invariably fatal. With current therapy,[8] complete response rates of over 50% are reported, and the median duration of survival is upward of 5 years.[9] Agents to reverse the misfolding of the protein and render it soluble would be ideal, but they are currently investigational. The source of the immunoglobulin light chain is the clonal plasma cell population in the bone marrow. All known therapies are directed at destruction of the plasma cell clone.

The two treatment choices are traditional-dose chemoimmunotherapy with or without high-dose chemotherapy with autologous stem cell transplantation. Most patients are not candidates for high-dose therapy because of age, advanced cardiac dysfunction, or renal insufficiency. High-dose melphalan is a feasible approach in selected patients with light chain amyloidosis and is associated with a high rate of hematologic and organ responses that lead to prolonged survival (Fig. 174-4). Current therapies include combinations of melphalan, cyclophosphamide, dexamethasone, bortezomib,[10] and lenalidomide. Treatment under expert oversight with a combination of daratumumab, which is a human monoclonal antibody against CD38 (1800 mg subcutaneously),[11] bortezomib (1.3 mg/m^2 weekly), cyclophosphamide (300 mg/m^2 orally weekly), and dexamethasone (40 mg weekly) can produce rapid and complete hematologic responses in the majority of patients with light chain amyloidosis with few side effects.[A1] Even without the daratumumab, the triplet of bortezomib, cyclophosphamide, and dexamethasone can result in slightly more than 50% of patients not requiring additional treatment for at least 7 years.[12] Effective plasma cell directed therapy has been associated with resolution of nephrotic syndrome, cardiac failure, and hepatomegaly.

For rescue therapy (Fig. 174-5), expert oversight is required. One option is pomalidomide plus dexamethasone.[13] Another option is to add daratumumab, which can provide a rapid hematologic response and a 2-year survival of about 75% as a single agent.[14,A2] Investigational venetoclax appears to have high activity in patients whose plasma cells express t(11;14).

For patients with chronic renal failure, kidney transplantation (Chapter 117) is an option.[15] Antibodies to amyloid fibrils are being tested.

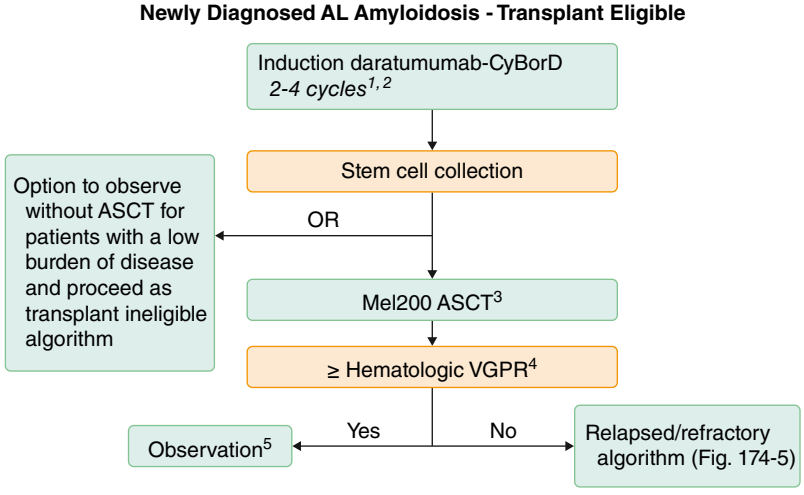

FIGURE 174-4. Treatment for newly diagnosed AL amyloidosis patients who are transplant-eligible. [1]Consider adding doxycycline for at least a year. [2]If daratumumab is not accessible, CyBorD is an acceptable alternative regimen (weekly bortezomib only). [3]For CrCl <30, use Mel 140 mg/m^2. [4]Decision to change therapy if in VGPR but < CR is based on a number of clinical factors, re-refer to amyloid center of excellence. [5]For patients with overt multiple myeloma, use myeloma-type maintenance; consider for BMPCs ≥20% and high-risk FISH (del 17p, t(4;14), t(14;16) and t(14;20)). Please refer for myeloma mSMART guidelines for choice of maintenance. https://www.mayoclinic.org/medical-professionals/cancer/news/msmart-a-clear-and-simple-guide-for-treating-patients-with-multiple-myeloma/mqc-20506750. ASCT = autologous stem cell transplant; BMPC = bone marrow plasma cells; CyBorD = cyclophosphamide, bortezomib, dexamethasone; Mel = melphalan; VGPR = very good partial remission.

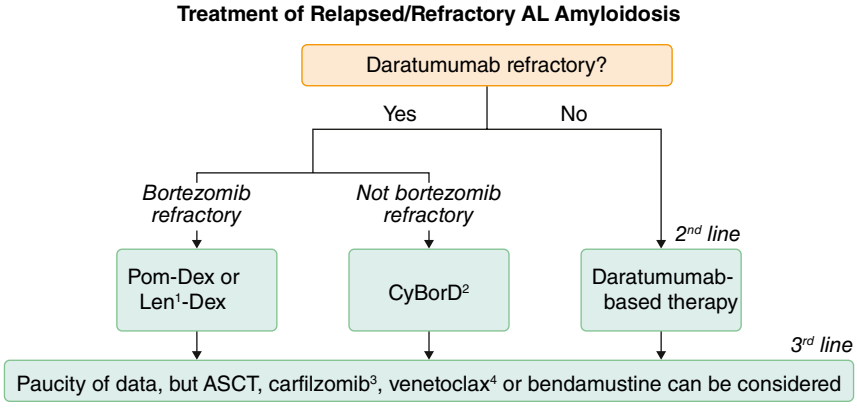

FIGURE 174-5. Treatment of relapsed/refractory AL amyloidosis. [1]Starting dose of lenalidomide should be no higher than 15 mg/d. [2]Melphalan-dexamethasone and ixazomib-dexamethasone are appropriate if patient has significant neuropathy. [3]Not recommended in patients with cardiac involvement. [4]For patients with t(11;14). Be cautious of infection risk. ASCT = autologous stem cell transplant; CyBorD = cyclophosphamide, bortezomib, dexamethasone; Dex = dexamethasone; Len = lenalidomide; Pom = pomalidomide.

PROGNOSIS

Patients who have AL amyloidosis and a baseline difference of less than 50 mg/L between circulating involved and uninvolved free light chain (i.e., low free light chain burden) have a better outcome.[16] This assay also can measure the therapeutic effect of interventions because the light chain level is quantifiable and reproducible.[17] Successful therapy is characterized by a 50% reduction in the abnormal free light chain level, but it is uncertain whether patients who do not achieve this level of response should be subjected to more intensive treatment in an effort to remove this pathogenic amyloid serum precursor.

The outcome of patients with light chain amyloidosis is highly dependent on the extent of cardiac involvement (Chapter 47), including myocardial dysfunction and arrhythmias. Doppler echocardiography allows quantitative measurements of diastolic function and reflects the slowing of blood flow into the ventricular chamber as the noncompliant left ventricle fills. This "stiffness," measured by the deceleration time, provides useful information and correlates well with survival.

Cardiac biomarkers are extremely sensitive measures of myocardial function, are reproducible, and can be used not only for prognosis but also to follow cardiac response after effective therapy.[18] The serum troponin value is a powerful predictor of survival in patients with amyloidosis, and the N-terminal pro–brain natriuretic peptide value also predicts survival. With the advent of routine hemodialysis, death due to renal failure is uncommon.

OTHER SYSTEMIC AMYLOIDOSES

ATTRwt AMYLOIDOSIS

ATTRwt amyloidosis (formerly known as senile systemic amyloidosis) results from the deposition of a normal serum protein, transthyretin, in the myocardium. Most patients are older than age 70 years.

The clinical presentation of ATTRwt is not distinguishable from that of cardiac light chain amyloidosis. The diagnosis of ATTRwt is supported when a cardiac technetium pyrophosphate scan is positive (see E-Fig. 44-4) in the absence of a monoclonal protein. ATTRwt is the only type of amyloid that can be made without a tissue diagnosis. When a monoclonal protein is present, however, confirmation of the type of amyloid requires analysis of the Congo red–positive tissues by mass spectrometry or immunoelectron microscopy.

TREATMENT AND PROGNOSIS

Tafamidis (61 mg once daily), an oral agent that prevents misfolding of TTR into amyloid configuration, is the only approved therapy for ATTRwt. Elevated levels of NT-pro-brain natriuretic peptide and/or troponin, a reduced eGFR, and a decreased left ventricular ejection fraction are adverse risk factors. The median survival is 3.6 years.

FAMILIAL AMYLOIDOSIS

Familial (or hereditary) amyloidosis is uncommon in the United States and represents only 3% of cases of systemic amyloidosis. The precursor protein of the amyloid determines the clinical phenotype (Table 174-1).

Among the 100 or more transthyretin point mutations, one important form of familial amyloidosis in the United States is a *TTR* allele in which isoleucine is substituted for valine at gene position 152 resulting in the TTR protein V122I. Approximately 4% of Black Americans are heterozygotes for *ATTRV122I*, which increases the risk of incident heart failure by 50% but not the risk of mortality.[19] The gene mutation *ATTRV50M* causes a late-onset transthyretin familial amyloid polyneuropathy. Less common causes of hereditary systemic amyloidoses include destabilizing mutations or deletions of lysozyme, apolipoprotein AI,[20] apolipoprotein AII, apolipoprotein AIV, fibrinogen α chain, gelsolin, and cystatin C.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients may present with the full clinical spectrum associated with amyloidosis, including cardiomyopathy, peripheral neuropathy, autonomic neuropathy, and/or proteinuria, depending on the precursor protein.[21] Diagnosis, typically by biopsy in the early stages, is essential to allow for timely treatment to prevent or delay disease progression. Myocardial radiotracer uptake on bone scintigraphy using technetium (Tc^{99}) pyrophosphate (PYP; see E-Fig. 44-4) or 3,3-diphosphono-1,2-propanodicarboxylic acid (DPD) is greater than 99% sensitive and 86% specific for cardiac mutant and wild-type ATTR cardiac amyloidosis, with false-positive results almost exclusively from uptake in patients with cardiac light chain amyloidosis.[22] Guidelines encourage genetic counseling and routine presymptomatic genetic testing.[23]

TREATMENT AND PROGNOSIS

Transthyretin amyloid cardiomyopathy is now a treatable condition.[24,25] Tafamidis (20 to 80 mg daily), which binds noncooperatively to the two thyroxine sites on the tetrameric form of transthyretin and thereby prevents its dissociation into monomers, can slow progression of transthyretin amyloid cardiomyopathy and reduce all-cause mortality.[A3] At 30 months, the 80-mg dose appears to be more efficacious, in terms of cardiac function as well as mortality.[A4] Patisiran (generally 0.3 mg/kg with a capped dose of 30 mg intravenously every 3 weeks) is a small interfering RNA drug that blocks the production of transthyretin; it can decrease ventricular wall thickness, reduce adverse cardiac outcomes,[A5] and slow the progression of the polyneuropathy.[A6] Similarly, inotersen (284 mg subcutaneously weekly) also can slow the progression of polyneuropathy and improve quality of life.[A7] Diflunisal (an FDA–approved generic nonsteroidal anti-inflammatory drug at 250 mg twice daily) can slow the rate of progression of the familial TTR amyloidosis–associated polyneuropathy.[26] Diflunisal complexes to the thyroxine binding sites on the tetrameric form of transthyretin, stabilizes it, and thus inhibits the release of the transthyretin monomer required for amyloidogenesis.

Because this disease is characterized by systemic accumulation of polymerized transthyretin in the peripheral nerves and systemic organs, liver transplantation stops the major production of amyloidogenic transthyretin. Selected patients with familial amyloidosis and polyneuropathy have benefited from liver transplantation. In the future, the availability of gene silencing therapy[27] may reduce the need for liver transplantation.

For transthyretin-related amyloidosis, the median historical survival was 5 to 15 years depending on the organs involved. The effect of newer medications on life expectancy is encouraging but uncertain. The estimated probability of 10-year survival in patients with familial amyloid polyneuropathy can be as high as 90 to 100%.

SECONDARY SYSTEMIC AMYLOIDOSIS

Systemic secondary amyloidosis is now the rarest form of amyloidosis in Western countries.[28] Previously, secondary amyloidosis was a well-recognized consequence of uncontrolled sustained inflammation, usually infectious, and causes included tuberculosis and osteomyelitis. Cystic fibrosis (Chapter 77), bronchiectasis (Chapter 78), decubitus ulcers, and skin abscesses related to subcutaneous injection of illicit drugs remain modern-day infectious causes. Secondary amyloidosis can also occur in patients with difficult-to-control inflammatory syndromes, including Crohn disease (Chapter 127), juvenile arthritis, and ankylosing spondylitis (Chapter 244). The number of patients who develop secondary amyloidosis related to rheumatic diseases has declined markedly, at least in part because of the use of disease-modifying antirheumatic therapy.[29] Familial forms of secondary amyloidosis are associated with familial periodic fever syndromes, the most common being familial Mediterranean fever (Chapter 254) due to mutations in the tumor necrosis factor receptor.

Organ damage results from the extracellular deposition of proteolytic fragments of the acute phase reactant serum amyloid A as amyloid fibrils. The distribution of deposits is mostly in the kidney, spleen, liver, and intestines.

Secondary amyloidosis patients typically present with proteinuria, nephrotic syndrome, or renal dysfunction. Diarrhea related to intestinal involvement (22%) and thyromegaly (9%) also occur.

TREATMENT

Suppression of the inflammatory process results in regression of tissue amyloid deposits. Therefore, monitoring of patients with chronic, active inflammatory disease by serial testing of serum amyloid A, C-reactive protein, microalbuminemia, proteinuria, and other indicators of amyloid development, as well as possibly determination of the *SAA1* genotype, can guide management. Anti–tumor necrosis factor-α agents have markedly reduced the incidence of secondary amyloidosis from inflammatory arthritis. Interleukin-1 inhibitors (e.g., anakinra) have been used successfully under expert oversight for patients who have inherited periodic fever syndromes (Chapter 254).

LOCALIZED AMYLOIDOSIS

Localized amyloidosis can be confused with systemic amyloidosis. However, patients with localized amyloidosis do not have a demonstrable monoclonal protein in the serum or urine and have a normal free light chain ratio. The location of the amyloid deposits also can be a clue to the localized nature.

Typical sites for localized amyloid deposition include the ureter, bladder, urethra, and prostate. Most forms of cutaneous amyloidosis are localized, although nodular cutaneous amyloidosis can occur in systemic light chain amyloidosis. Tracheobronchial and laryngeal amyloidosis and nodular pulmonary amyloidosis are localized and are not associated with a plasma cell dyscrasia. Nodular pulmonary amyloidosis is often diagnosed after thoracotomy or transcutaneous biopsy. Most cases of laryngeal amyloidosis are found when the patient presents to an otorhinolaryngologist with hoarseness and amyloid deposits are found on endoscopic biopsy. The localized amyloidosis found in Alzheimer disease (Chapter 371) is chemically unrelated to light chain amyloidosis, and patients with light chain amyloidosis do not have an increased risk of dementia.

TREATMENT AND PROGNOSIS

Management can be supportive or localized to the deposition, and patients generally do not require systemic therapy. For genitourinary amyloidosis, therapy entails cystoscopic resection or intravesical instillation of dimethyl sulfoxide. Laryngeal, tracheobronchial, and cutaneous amyloidosis can be treated with a variety of local agents under expert supervision with varying degrees of success. Overall, however, localized amyloidosis has a much better prognosis than does systemic amyloidosis.

175 TUMORS OF THE CENTRAL NERVOUS SYSTEM

INGO K. MELLINGHOFF AND LISA M. DEANGELIS

Central nervous system (CNS) tumors can involve the brain or the spinal cord, may be benign or malignant, and may be primary or metastatic. In the United States, about 80,000 new primary brain tumors and other nervous system tumors are diagnosed annually, and about one-third of primary CNS tumors are malignant. In contrast, intracranial metastases are five times more common than primary brain tumors.

Over 100 different types and subtypes of brain and spinal cord tumors arise from cells that make up the CNS (Table 175-1). Because CNS tumors grow within the CNS and rarely if ever metastasize to other organs, conventional tumor staging approaches are not applicable, so histopathologic and molecular features are used to categorize CNS tumors. Histopathologic features that suggest more aggressive growth include cytologic atypia, increased mitotic rate, microvascular proliferation, and regional necrosis. Tumors lacking these features are still able to grow within the CNS and to cause progressive neurologic disability, and they may acquire a more malignant phenotype over time. Tumor grading includes histologic features[1,2] as well as molecular information. In difficult cases, DNA methylation patterns can help assign a tumor subtype.

BRAIN TUMORS

Extra-axial primary brain tumors arise within the intracranial cavity but are not tumors of brain tissue. Although they produce neurologic symptoms and signs by compressing the underlying brain, almost all extra-axial tumors are benign. Since the brain is rarely invaded, complete surgical excision is often feasible.

In contrast, intra-axial primary brain tumors tend to invade brain tissue diffusely, and none can be completely excised surgically. Most primary intra-axial brain tumors are gliomas, including the astrocytomas, oligodendrogliomas, and ependymomas.

CLINICAL MANIFESTATIONS

A patient with a brain tumor can present with generalized and/or lateralizing symptoms and signs. Generalized symptoms, which include headache, lethargy, personality change, nausea, and vomiting, typically reflect the increased intracranial pressure that often accompanies cerebral tumors. Lateralizing symptoms, which reflect the specific location of the tumor, include hemiparesis, hemisensory deficits, aphasia, visual field impairment, and seizures (Table 175-2).

175 TUMORS OF THE CENTRAL NERVOUS SYSTEM

INGO K. MELLINGHOFF AND LISA M. DEANGELIS

Central nervous system (CNS) tumors can involve the brain or the spinal cord, may be benign or malignant, and may be primary or metastatic. In the United States, about 80,000 new primary brain tumors and other nervous system tumors are diagnosed annually, and about one-third of primary CNS tumors are malignant. In contrast, intracranial metastases are five times more common than primary brain tumors.

Over 100 different types and subtypes of brain and spinal cord tumors arise from cells that make up the CNS (Table 175-1). Because CNS tumors grow within the CNS and rarely if ever metastasize to other organs, conventional tumor staging approaches are not applicable, so histopathologic and molecular features are used to categorize CNS tumors. Histopathologic features that suggest more aggressive growth include cytologic atypia, increased mitotic rate, microvascular proliferation, and regional necrosis. Tumors lacking these features are still able to grow within the CNS and to cause progressive neurologic disability, and they may acquire a more malignant phenotype over time. Tumor grading includes histologic features[1,2] as well as molecular information. In difficult cases, DNA methylation patterns can help assign a tumor subtype.

BRAIN TUMORS

Extra-axial primary brain tumors arise within the intracranial cavity but are not tumors of brain tissue. Although they produce neurologic symptoms and signs by compressing the underlying brain, almost all extra-axial tumors are benign. Since the brain is rarely invaded, complete surgical excision is often feasible.

In contrast, intra-axial primary brain tumors tend to invade brain tissue diffusely, and none can be completely excised surgically. Most primary intra-axial brain tumors are gliomas, including the astrocytomas, oligodendrogliomas, and ependymomas.

CLINICAL MANIFESTATIONS

A patient with a brain tumor can present with generalized and/or lateralizing symptoms and signs. Generalized symptoms, which include headache, lethargy, personality change, nausea, and vomiting, typically reflect the increased intracranial pressure that often accompanies cerebral tumors. Lateralizing symptoms, which reflect the specific location of the tumor, include hemiparesis, hemisensory deficits, aphasia, visual field impairment, and seizures (Table 175-2).

ABSTRACT

About 80,000 new primary tumors of the central nervous system are diagnosed annually in the United States, and five times as many intracranial metastases from a wide variety of other primary sites are diagnosed. Both types of tumors are addressed in this chapter. The new World Health Organization classification of primary brain tumors has incorporated some significant changes, particularly including molecular features in some categories of gliomas, ependymomas, and embryonal tumors in recognition of their prognostic value. Magnetic resonance imaging is far superior to computed tomography in diagnosis. The mainstays of therapy are surgery, radiation therapy, chemotherapy, and combinations of these modalities. Data from controlled clinical trials can often guide therapy, but experimental modalities are frequently tried in progressive cases.

TABLE 175-1 WORLD HEALTH ORGANIZATION CLASSIFICATION (WHO) OF BRAIN TUMORS

GLIOMAS, GLIONEURONAL TUMORS, AND NEURONAL TUMORS
Adult-type Diffuse Gliomas
Astrocytoma, IDH-mutant
Oligodendroglioma, IDH-mutant, and 1p/19q-codeleted
Glioblastoma, IDH-wildtype
Pediatric-type Diffuse Low-grade Gliomas
Pediatric-type Diffuse High-grade Gliomas
Diffuse midline glioma, H3 K27-altered
Diffuse hemispheric glioma, H3 G34-mutant
Diffuse pediatric-type high-grade glioma, H3-wildtype and IDH-wildtype
Infant-type hemispheric glioma
Circumscribed Astrocytic Gliomas
Pilocytic astrocytoma
Pleomorphic xanthoastrocytoma
Subependymal giant cell astrocytoma
Glioneuronal and Neuronal Tumors
Ependymal Tumors
CHOROID PLEXUS TUMORS
EMBRYONAL TUMORS
Medulloblastoma
Other CNS embryonal tumors
PINEAL TUMORS (INCLUDING PINEOBLASTOMA, OTHERS)
CRANIAL AND PARASPINAL NERVE TUMORS (INCLUDING NEUROFIBROMA, SCHWANNOMA, OTHERS)
MENINGIOMAS
MESENCHYMAL, NON-MENINGOTHELIAL TUMORS
MELANOCYTIC TUMORS
HEMATOLYMPHOID TUMORS
Lymphomas, including Primary CNS Lymphoma
Histiocytic tumors
GERM CELL TUMORS
TUMORS OF THE SELLAR REGION
Craniopharyngioma
Pituitary adenoma/PitNET

CNS = central nervous system; IDH = isocitrate dehydrogenase; PitNET = pituitary neuroendocrine tumor. Abridged and modified from Louis DN, Perry A, Wesseling P, et al. The 2021 WHO classification of the tumors of the central nervous system: a summary. *Neuro Oncol*. 2021;23:1231-1251.

TABLE 175-2 FOCAL CLINICAL MANIFESTATIONS OF BRAIN TUMORS

FRONTAL LOBE	
Generalized seizures; focal motor seizures (contralateral); expressive aphasia (dominant side); behavioral changes; dementia; gait disorders; incontinence; hemiparesis (contralateral)	
BASAL GANGLIA	
Hemiparesis (contralateral); movement disorders (rare)	
PARIETAL LOBE	
Receptive aphasia (dominant side); spatial disorientation (nondominant side); cortical sensory dysfunction (contralateral); hemianopia (contralateral); agnosias	
OCCIPITAL LOBE	
Hemianopia (contralateral); visual disturbances (unformed)	
TEMPORAL LOBE	
Complex partial (psychomotor) seizures; generalized seizures; olfactory and complex visual auras; behavioral changes; visual field defect; language disorder (dominant side)	
CORPUS CALLOSUM	
Dementia (anterior); memory loss (posterior); asymptomatic (middle); behavioral changes	
THALAMUS	
Sensory loss (contralateral); language disorder (dominant side); behavioral changes	
MIDBRAIN/PINEAL	
Paresis of vertical eye; pupillary abnormalities; precocious puberty (boys)	
SELLA/OPTIC NERVE/PITUITARY	
Endocrinopathy; bitemporal hemianopia; monocular visual defects; ophthalmoplegia (cavernous sinus)	
PONS/MEDULLA	
Cranial nerve dysfunction; ataxia; nystagmus; spasticity; weakness; sensory loss	
CEREBELLOPONTINE ANGLE	
Deafness (ipsilateral); loss of facial sensation (ipsilateral); facial weakness (ipsilateral); ataxia	
CEREBELLUM	
Ataxia (ipsilateral or gait); nystagmus	

Symptoms of brain tumors can be produced by tumor that directly invades the brain parenchyma, when tumor and edema compress brain tissue, when obstruction to cerebrospinal fluid (CSF) is directly caused by the tumor or by a shift of brain tissue, and when herniation occurs. Invasion and compression typically produce lateralizing symptoms, whereas obstruction of the flow of cerebrospinal fluid and herniation typically produce generalized symptoms but can also cause false localizing signs, such as an abducens nerve palsy as a result of diffuse increased intracranial pressure.

Headache (Chapter 367) is a presenting symptom of approximately 35% of brain tumors. It is more common in younger than in older patients and more common in patients who have rapidly growing tumors than in patients whose tumors have evolved slowly. Local growth of the tumor may cause mental and cognitive abnormalities (e.g., aphasia, alexia, agnosia) or general impairment (e.g., lethargy, confusion, word finding difficulty, apathy).

Most patients have symptoms that progress during a week to a few months. A sudden intensification of symptoms may precipitate the patient's initial visit to the physician, but a careful history usually reveals symptoms that predated the acute deterioration and slowly worsened over time. Two exceptions are the new appearance of a seizure in a previously asymptomatic individual (Chapter 372) and sudden hemorrhage into a tumor.

Seizures (Chapter 372) affect approximately one-third of patients with brain tumors, and they are especially common as the presenting and only symptom of a low-grade tumor. The seizures, which are focal because they originate at the site of the tumor, may remain restricted (e.g., focal motor seizures), or they may generalize secondarily to produce loss of consciousness, sometimes so quickly that the focal signature is missed by the patient or even an observant witness.

DIAGNOSIS

A careful history and physical examination (Chapter 366) should assess cognitive function (Chapter 361) and search for any lateralizing signs. Routine hematologic and blood chemistry tests should be obtained to exclude a metabolic cause of mental status changes (Chapter 361). However, urgent brain imaging is required when the diagnosis of a brain tumor is suspected.

Brain Imaging

Magnetic resonance imaging (MRI) should be performed both without and with intravenous administration of gadolinium, preferably using a standardized brain tumor imaging protocol. A well-performed MRI identifies any intracranial tumor, and a normal MRI effectively excludes a neoplasm.

The MRI of some extra-axial tumors (e.g., acoustic neuromas, meningiomas) is so characteristic that histologic confirmation is not required. A non–contrast-enhancing infiltrative lesion that is visible primarily on T2-weighted or fluid-attenuated inversion recovery images is most consistent with a low-grade glioma (Fig. 175-1). A contrast-enhancing lesion with an area of central necrosis and surrounding edema is most likely to be a glioblastoma or possibly a brain metastasis.

MRI is far superior to computed tomography (CT) for the diagnosis of brain tumors and should be obtained in all patients with a suspected intracranial tumor. A CT scan, even with the administration of contrast material, may miss low-grade tumors and tumors in the posterior fossa, so a CT scan should be obtained only in patients who cannot undergo MRI.

In less clear cases, functional imaging techniques can be helpful to distinguish a brain tumor from other CNS lesions. Examples include cerebral blood volume (perfusion MRI), loss of tumor cellularity (diffusion-weighted MRI), the flow of contrast agent across a damaged blood-brain barrier (dynamic contrast-enhanced MRI), or the abundance of certain metabolites (MR spectroscopy).

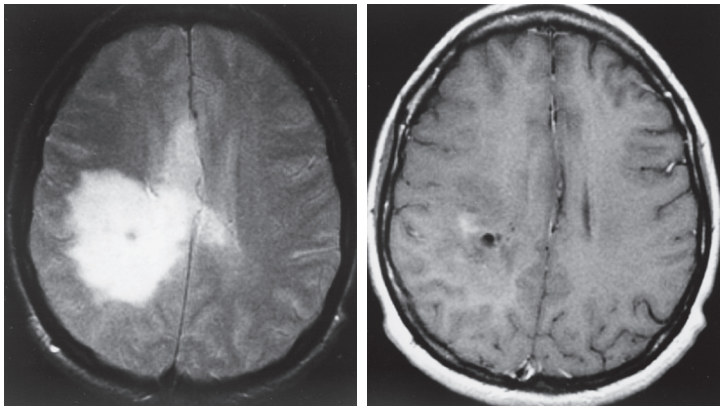

FIGURE 175-1. Glioma. Magnetic resonance imaging of a low-grade glioma. *Left*, T2-weighted image. *Right*, T1-weighted image, gadolinium contrast with minimum enhancement.

Malignant tumors, for example, are associated with an increased choline : *N*-acetylaspartate ratio and may contain areas with elevated levels of lactate and lipid. Functional MRI, which measures cerebral blood flow when areas of cortex are activated, may guide a safer and more complete surgical resection by localizing critical neurologic functions and their relationship to the tumor. Angiography no longer has a diagnostic role, but angiographic embolization is occasionally useful preoperatively to reduce the vascularity of some meningiomas, thereby making a complete resection safer.

Biopsy

Biopsy is typically part of a surgical procedure to remove the tumor to the greatest degree that is safe. However, most lesions that cannot be resected are still amenable to biopsy for diagnostic purposes. Stereotactic biopsy can reach lesions in almost any area of the brain with minimal morbidity. The risks of stereotactic biopsy include an inadequate tissue sample to make a diagnosis, a tissue sample that does not accurately reflect the most malignant grade of the tumor, and a procedure-related complication. Hemorrhage that causes neurologic impairment occurs in only 2% of stereotactic biopsies, typically in patients with glioblastomas. Unfortunately, some tumors, such as brain stem gliomas, are in such critical locations that biopsy should not be attempted.

Other Diagnostic Approaches

Electroencephalography (EEG) can be useful when a patient with a brain tumor has prolonged or unexplained confusion or stupor and for whom nonconvulsive status epilepticus is a consideration. Intraoperative monitoring is used frequently to help guide resection of epileptogenic cortex adjacent to or within the brain tumor tissue or to perform intraoperative mapping of critical functions to facilitate a safe, complete resection.

Cerebrospinal fluid analysis has a limited role in the diagnosis of most intracranial neoplasms. In primary CNS lymphoma (Chapter 171), however, the diagnosis may be established on cerebrospinal fluid cytologic examination in about 15% of patients. The sensitivity of cerebrospinal fluid cytology in the diagnosis of CNS lymphoma increases when it is combined with flow cytometry and is further enhanced by immunophenotypic and molecular genetic analyses of the cerebrospinal fluid. Rarely, a lumbar puncture is required to exclude inflammatory conditions or other processes that may be confused with a primary brain tumor. Lumbar puncture must be avoided in patients with cerebellar tumors because the release of pressure through the spinal needle may result in herniation of the cerebellar tonsils through the foramen magnum. The ability to detect tumor-derived DNA and circulating tumor cells in cerebrospinal fluid from some patients with CNS tumors may be helpful to monitor the tumor's evolution and response to therapy without the need for neurosurgical procedures.

Differential Diagnosis of Brain Tumors

Patients who present with symptoms of raised intracranial pressure or the new onset of central neurologic symptoms, such as hemiparesis or seizure, must be evaluated urgently. Prompt neuroimaging discloses a mass, and the radiographic features narrow the differential diagnosis (Table 175-3). Extra-axial tumors, such as a meningioma or acoustic neuroma, can be confused with a dural metastasis. Low-grade intra-axial tumors, which are nonenhancing on MRI, have been confused with infections such as herpes encephalitis (Chapter 383) when they involve the temporal lobe. Contrast-enhancing intra-axial tumors can be confused with a stroke (Chapter 376), brain abscess (Chapter 382), or focal plaque of demyelination (Chapter 380). Subacute infarction can show brisk contrast enhancement, usually in a gyral pattern, unlike brain tumors in which enhancement is primarily in the white matter; however, the two are occasionally indistinguishable radiographically. Brain abscesses (Fig. 382-1) typically have a thinner enhancing wall than a malignant tumor and have restricted diffusion. Despite careful evaluation, patients thought to have a malignant glioma occasionally are found at surgery to have a brain abscess. A single large plaque of demyelination can also be confused radiographically with a brain tumor and sometimes the diagnosis can be established only by biopsy.

When MRI suggests a primary brain tumor, an extensive systemic search for a possible source of metastasis is rarely required. Brain metastases are more common than primary brain tumors, but most occur in patients with known cancer, typically with active systemic disease. If an obvious systemic cancer is not revealed by a thorough physical examination, chest radiograph, routine blood tests, and urinalysis, the patient should proceed to craniotomy. Even if a brain metastasis is found at surgery, resection of a single brain metastasis is the appropriate treatment, and the pathologic examination of the lesion guides the subsequent search for the primary tumor.

TABLE 175-3 DIFFERENTIAL DIAGNOSIS OF INTRACRANIAL TUMORS

INFECTION
Brain abscess (Chapter 382)
Bacterial
Fungal
Parasitic (e.g., cysticercosis; Chapter 325)

Venous angiomas (Chapter 377)
CONGENITAL ABNORMALITIES
Cortical dysplasia (Chapter 385)
Heterotopia (Chapter 385)

TREATMENT

The treatment for all brain tumors can be divided into two main categories: symptomatic therapy and tumor-directed therapy (Table 175-4). Symptomatic treatment addresses cerebral edema, thromboembolic disease, and seizures, all of which can contribute substantially to clinical symptoms caused by the tumor.

Management of Symptoms

Corticosteroids (typically dexamethasone starting at 8 to 12 mg/day) decrease the vasogenic edema that often surrounds primary and metastatic brain tumors. Clinical improvement may begin within minutes, and patients frequently improve dramatically within 24 to 48 hours. This dose is then adjusted to find the lowest dose that alleviates neurologic symptoms. Once- or twice-daily dosing is preferred for maintenance therapy over more frequent dosing. After definitive treatment is instituted, many patients can be tapered off their corticosteroid completely. Chronic high-dose corticosteroid therapy is associated with substantial side effects (Chapter 28) and should be avoided if possible. Common side effects include insomnia, steroid myopathy, gastrointestinal complications, and opportunistic infections. Patients who will be taking corticosteroids for 6 weeks or longer should receive prophylaxis against *Pneumocystis jirovecii* (Chapter 313). Antibodies that block the effects of vascular endothelial growth factor (VEGF), such as bevacizumab, can be very effective in the management of symptomatic cerebral edema and can reduce corticosteroid requirements.

Venous thromboembolism affects about 25% of patients who have brain tumors. All patients undergoing neurosurgery should have pneumatic compression boots in the postoperative period to reduce the incidence of venous thromboembolism. Prophylactic anticoagulants (Chapter 68) also have been used successfully in the immediate postoperative period without increasing postoperative hemorrhage. Appropriately regulated anticoagulation (Chapter 70) is the optimal therapy for deep vein thrombosis and is not associated with an increased risk for intracerebral hemorrhage. Inferior vena cava filters can be used for patients who have deep vein thrombi or pulmonary emboli and who cannot be fully anticoagulated.

TABLE 175-4 TREATMENT OF BRAIN TUMORS

SYMPTOMATIC TREATMENT
Glucocorticoids
Antiepileptics
Venous thromboembolism prophylaxis and treatment
TUMOR-DIRECTED THERAPY
Surgery
Radiation therapy
Chemotherapy or other systemic therapy

Anticonvulsant medications (Chapter 372) are administered to any patient who has had a seizure, but prophylactic anticonvulsants should not be prescribed for patients who have never had a seizure, except in the immediate perioperative period. When used, the dose of antiepileptic agents generally should be tapered beginning 2 to 3 weeks after craniotomy.

Tumor-Directed Therapies

Surgery

Complete excision is the goal for a primary brain tumor. Surgical excision can often be accomplished for primary extra-axial tumors, such as meningiomas and acoustic neuromas, unless their intracranial location makes resection impossible. Tumors of the skull base are particularly difficult to remove, and partial resection for decompression is often performed to preserve neurologic function. The safe boundaries for resecting cortical lesions while preserving function often can be elucidated by preoperative functional MRI and intraoperative cortical mapping. However, lesions involving critical structures, such as the brain stem or thalamus, cannot be excised safely.

Complete excision can cure an extra-axial primary brain tumor and is associated with prolonged survival and better neurologic outcome, even in patients with primary intra-axial tumors. In patients with malignant and lower grade gliomas, gross total excision, as measured by postoperative neuroimaging, is associated with prolonged survival. However, most low-grade gliomas are not amenable to gross total excision, and only partial excision is usually feasible. In patients with high-grade gliomas, macroscopic tumor frequently can be removed completely, but microscopic disease that infiltrates surrounding brain tissue always remains.

Radiation Therapy

A course of external beam radiation therapy is delivered in small daily fractions to a total cumulative dose usually between 45 and 60 Gy. Dividing the treatment into small daily fractions permits sublethal repair in normal tissues and markedly reduces the neurologic toxicity that is associated with cerebral irradiation. External beam radiation, which is the most effective nonsurgical treatment of brain tumors, doubles median survival time of patients with malignant primary brain tumors or metastatic lesions. Radiation therapy can also be useful for recurrent meningiomas and acoustic neuromas. However, it only rarely cures any of these lesions, and most patients develop recurrent disease despite maximal radiation therapy.

Stereotactic radiosurgery delivers high fractions of focused radiation therapy that spare normal surrounding tissue. The technique is generally limited to tumors that are 3 cm in diameter or smaller and is less useful for malignant gliomas because of their infiltrative nature.

The neurologic complications of radiation therapy, which are usually observed months to years after completion of treatment, include radionecrosis, dementia, and leukoencephalopathy. The incidence is reported as less than 5%, and most patients die of their brain tumor before the delayed consequences of treatment can be observed. However, in long-term survivors (e.g., patients with lower grade glioma or children with medulloblastoma), the late consequences of radiation therapy are important. Dementia accompanying radiation-induced leukoencephalopathy can progress and result in severe neurologic impairment. Radionecrosis can mimic recurrent tumor with a large contrast-enhancing lesion on MRI. Corticosteroids under expert supervision can reduce the edema and sometimes are sufficient to treat small areas of radionecrosis. However, if the lesion is sufficiently large, resection may be required to decompress the mass and reduce the corticosteroid requirement. Laser interstitial thermal therapy is also a possible therapeutic approach for intractable radionecrosis.

Systemic Therapy

Systemic medical therapies vary depending on the type and grade of the tumor. Currently, all such regimens are palliative rather than curative, except for some patients who have CNS lymphomas.

SPECIFIC TYPES OF PRIMARY BRAIN TUMORS

MENINGIOMAS

EPIDEMIOLOGY AND PATHOBIOLOGY

Meningiomas are the most common primary CNS tumors and are usually benign. Between 10 and 15% of meningiomas are atypical or malignant variants with a more aggressive course.[3] Meningiomas are more common in women and may be multiple in about 10% of patients with sporadic meningioma.

FIGURE 175-2. Meningioma. Computed tomography scan with contrast enhancement of a meningioma in a patient who presented with mild cognitive deficits, illustrative of the size that a slow-growing tumor can attain in the brain. The tumor was completely resected.

Exposure to ionizing radiation elevates the risk for meningioma. Meningiomas are occasionally part of a familial syndrome and occur with increased frequency in patients with neurofibromatosis type 2 (NF2; Chapter 385). Inactivation of *NF2* is seen in approximately 50% of sporadic tumors. Other genes are also mutated frequently in meningioma (e.g., *SMO*, *AKT1*, *KLF4*, *TRAF7*), but the role of these alterations in the development or growth of meningioma remains to be defined.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Meningiomas grow slowly and produce symptoms that are insidious in onset and typically slowly progressive. Frequently, meningiomas are completely asymptomatic and are identified on neuroimaging done for another purpose, such as head trauma.

Tumors can reach a considerable size (Fig. 175-2), but they grow so slowly that the brain accommodates to the progressive compression. Meningiomas typically occur in specific locations: over the convexity, along the falx and parasagittal area, in the olfactory groove, at the base of the skull near the sphenoid bone, in the cavernous sinus (Fig. 175-3), in the cerebellopontine angle, and in the foramen magnum. Cortical and parasagittal tumors typically are manifested with seizures or progressive hemiparesis. Tumors in the anterior cranial fossa can cause slowly progressive cognitive and personality changes. Meningiomas at the base of the skull are manifested with cranial neuropathies and gait difficulties when the brain stem is compressed.

On MRI, meningiomas have a characteristic appearance consisting of a diffusely enhancing, dural-based lesion that is associated with a thin enhancing dural tail that extends from the tumor. The radiographic features are often so characteristic that biopsy is not required and surgery is performed for therapeutic purposes only. The radiographic differential diagnosis includes the less common hemangiopericytoma and dural metastasis. Most meningiomas are not accompanied by significant edema, but marked edema is seen with high-grade malignant lesions or the secretory variant.

TREATMENT AND PROGNOSIS

If small meningiomas are discovered in the absence of clinical symptoms or the symptoms are minor, lesions may be monitored with serial images because growth can be so slow. If treatment is indicated, complete resection is often curative, but even completely resected benign tumors may recur in as many as 20% of cases, so radiologic follow-up is essential. Tumors at the base of the skull often cannot be resected completely and tend to recur despite successive attempts at surgical resection. Stereotactic radiosurgery may be an alternative to surgery if the lesion is small or if patients have progressive or residual tumor.[4] External beam radiation therapy may slow progression of recurrent lesions and is essential for the treatment of malignant meningiomas.

DNA methylation profiling and determination of *CDKN2A/B* gene copy loss can provide prognostic information. No effective systemic therapy has been identified for recurrent meningioma.[5]

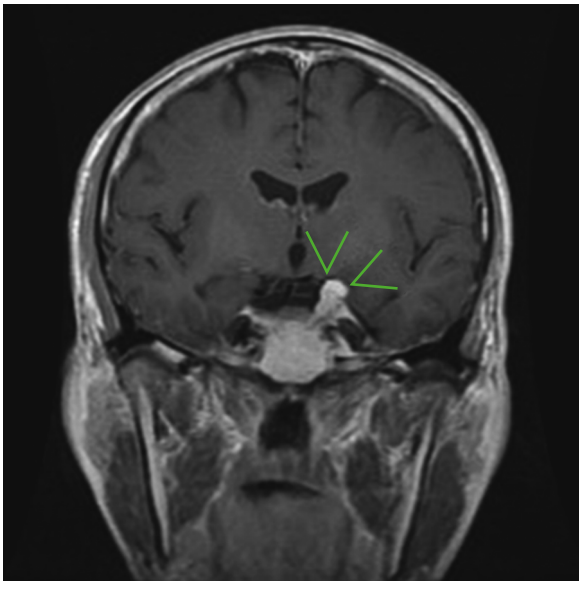

FIGURE 175-3. Skull base meningioma. A post-gadolinium coronal magnetic resonance image demonstrating a small left meningioma arising from the clinoid.

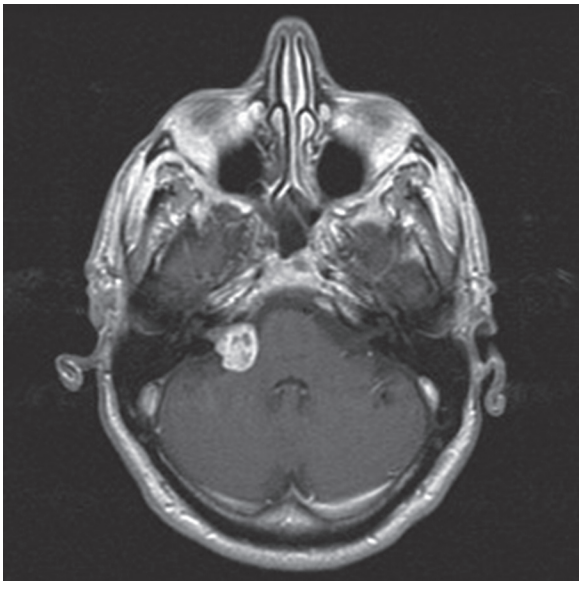

FIGURE 175-4. Vestibular schwannoma. A post-gadolinium magnetic resonance image demonstrating a large right vestibular schwannoma. The origin can be seen in the acoustic canal, but the tumor has grown into the cerebellopontine angle, where it is compressing the brainstem.

VESTIBULAR SCHWANNOMAS

Vestibular schwannomas, also called acoustic neuromas (Chapter 396), are benign tumors that arise from the eighth cranial nerve. Vestibular schwannomas are twice as common in women as in men, with a peak incidence between ages 40 and 60 years. Sporadic vestibular schwannomas are unilateral, whereas bilateral vestibular schwannomas are pathognomonic of neurofibromatosis type 2 (Chapter 385).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Vestibular schwannomas usually arise from the vestibular portion of the nerve and typically are manifest by unilateral hearing loss, sometimes preceded or accompanied by tinnitus and a sensation of dizziness or unsteadiness but not true vertigo (Chapter 396). The slow, progressive enlargement of the tumor produces ipsilateral facial numbness or weakness by compressing the fifth or seventh cranial nerve, respectively. Tumors originate within the internal auditory meatus but grow out of the acoustic canal and into the cerebellopontine angle, where they can compress the brain stem and cause ataxia and ipsilateral cerebellar signs.[6] Cranial MRI with gadolinium delineates even small acoustic neuromas with ease (Fig. 175-4).[7]

TREATMENT

Treatment is often surgical, but stereotactic radiosurgery is an effective alternative, especially for lesions smaller than 3 cm.[8] Tumors should be treated when they are small to preserve facial nerve function and hearing.

PITUITARY ADENOMAS

Pituitary adenomas are discussed in Chapter 205.

OTHER EXTRA-AXIAL PRIMARY BRAIN TUMORS

Pineal Tumors

Pineal region tumors include pineal parenchymal tumors, such as pineocytomas and the more aggressive pineoblastomas, and germ cell tumors, including germinomas and non-germinomatous germ cell tumors. Pineal region tumors all have a characteristic clinical presentation that includes Parinaud syndrome, which consists of paresis of upward gaze, poor pupillary reaction to light with brisk reaction on accommodation, impairment of convergence, and convergence-retraction nystagmus. Some of these lesions may also cause hydrocephalus and symptoms of increased intracranial pressure. Germinomas can be completely cured with focal radiation therapy, whereas non-germinomatous germ cell tumors are more aggressive and frequently relapse despite chemotherapy plus cranial irradiation.

Chordomas and Lipomas

Chordomas are rare tumors of residual notochordal tissue. They usually occur at the base of the skull, are locally invasive, and are characterized by multiple recurrences despite surgery and radiation therapy. Proton radiotherapy may be recommended for skull-based lesions that are adjacent to critical structures. Small molecule inhibitors of oncogenic signaling pathways (e.g., imatinib, sorafenib) have been reported to produce responses and clinical benefit in some patients with recurrent disease.

Lipomas are benign tumors that can occur in midline structures, particularly near the corpus callosum. They can be cured by complete removal.

Arachnoid Cysts

Arachnoid cysts are not tumors but can manifest with headache, seizures, or focal neurologic symptoms if they become large enough to compress underlying brain tissue. Many are completely asymptomatic and are found incidentally on neuroimaging. Only symptomatic cysts require removal.

GLIOMAS

DEFINITION

Gliomas comprise a heterogenous group of tumors.[9] Diffuse gliomas include types that primarily occur in adults and types that primarily occur in children. All diffuse astrocytic tumors with mutations in isocitrate dehydrogenase (IDH) 1 or 2 are considered a single type *(astrocytoma, IDH-mutant)* and then graded as grade 2 (previously called *diffuse astrocytoma, IDH-mutant*), grade 3 (previously called *anaplastic astrocytoma, IDH mutant*), or grade 4 (previously called *glioblastoma, IDH-mutant*). For IDH-wildtype diffuse astrocytic tumors, the diagnosis of glioblastoma, IDH-wildtype should be made if the tumor shows microvascular proliferation or necrosis or 1 or more of 3 genetic parameters: a *TERT* promoter mutation, *EGFR* gene amplification, or combined gain of chromosome 7 and loss of chromosome 10. All grade 2 to 4 gliomas are diffuse and infiltrate widely into the brain, and the lower grade lesions may progress to higher grade tumors over time. Grade 1 lesions such as the pilocytic astrocytoma are extremely low-grade focal tumors that have a separate designation; they are more common in children, may be associated with neurofibromatosis type 1, and are often cured by complete surgical excision.

EPIDEMIOLOGY

Gliomas occur at any age, but the peak is ages 20 to 30 years for grade 2 lesions, age 40 years for grade 3 tumors, and age 55 to 60 years for glioblastoma. For all grades of glioma, men are more frequently affected than women, and White persons are significantly more frequently affected than Black persons. Gliomas are typically single lesions, but multifocal disease is seen in approximately 5% of patients with high-grade tumors.

PATHOBIOLOGY

At least 95% of gliomas are sporadic, and only 5% occur in patients with a family history of brain tumor. Furthermore, patients with a familial history of glioma usually do not fall into a well-recognized hereditary syndrome.

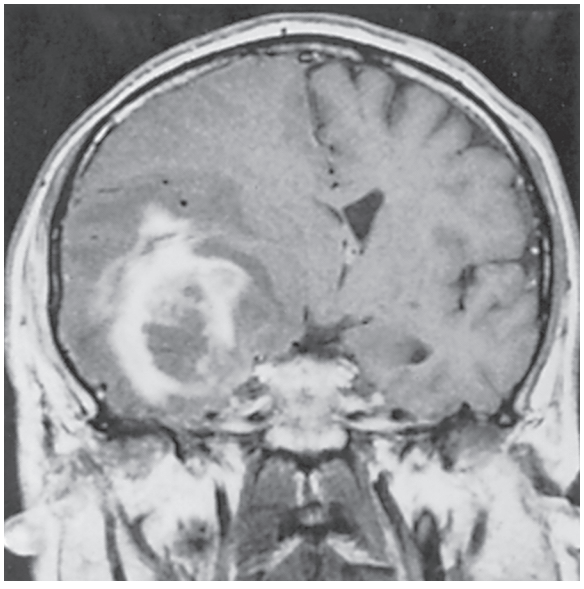

FIGURE 175-5. Temporal lobe glioblastoma. This T1-weighted gadolinium-enhanced magnetic resonance image shows a typical ring configuration of contrast material with central necrosis and marked mass effect.

Neurofibromatosis 1 (von Recklinghausen disease; Chapter 385) is associated with an increased incidence of gliomas, particularly in the optic pathway, hypothalamus, and brain stem. Gliomas also occur with increased frequency in Turcot and Lynch syndromes (Chapter 179), in which colorectal neoplasms are seen in association with a variety of CNS tumors. Somatic mutations of IDH1 and IDH2 have been identified in most lower grade gliomas.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with gliomas often present with seizures, headache, and lateralizing signs such as hemiparesis, aphasia, or a visual field deficit. IDH-mutant astrocytomas and oligodendroglial tumors have a variable course, with the oligodendrogliomas being more indolent. These young adults often present with isolated seizures that can be controlled easily with antiepileptic agents.

On MRI, low-grade gliomas typically appear as diffuse, non-enhancing lesions with a propensity to occur in the frontal lobe and insular cortex (see Fig. 175-1). High-grade gliomas, which typically enhance with contrast material, occur in the cortical white matter and are accompanied by significant surrounding edema. Glioblastomas frequently have regions of central necrosis (Fig. 175-5), and hemorrhage can occur in 5 to 8% of patients.

TREATMENT AND PROGNOSIS

For all gliomas, treatment frequently involves surgery, radiation therapy, and chemotherapy.[10] The surgical goal of complete removal of all visible disease is often impossible; even when possible, residual tumor remains. The extent of resection can be optimized using intraoperative MRI guidance and fluorescence-guided resection using 5-aminolevulinic acid. The adequacy of resection is best assessed on a postoperative MRI, without and with gadolinium, performed within 24 to 96 hours after surgery. Glioma resections with intraoperative stimulation and cortical mapping are associated with fewer severe neurologic deficits and more extensive resection. Surgical removal usually improves neurologic function and reduces dependency on corticosteroids.

Age is the single most important clinical prognostic factor; younger patients live substantially longer than older patients. Tumors of any histology or grade with an IDH mutation have a significantly better prognosis than the identical tumor that is IDH-wildtype. Performance status, duration of symptoms, and whether a complete resection has been achieved are also strong predictors of improved outcome and prolonged survival.

Glioblastoma, IDH-Wildtype, Grade 4

All glioblastomas should be treated with postoperative radiation therapy to a dose of approximately 60 Gy. Hypofractionated radiotherapy is superior to standard radiation therapy in elderly patients with glioblastomas, especially in patients older than age 70 years.

The alkylating agent temozolomide (75 mg/m^2 daily orally), administered concurrently with radiation therapy and followed by adjuvant temozolomide (150 to 200 mg/m^2 for 5 consecutive days every 4 weeks for six cycles), can significantly improve median survival from 12.1 months to 14.6 months and more than double the 2-year survival rate to 26% compared with radiation therapy alone. Patients whose tumors contain a methylated promoter of the O6-methylguanine-DNA methyltransferase (MGMT) DNA repair gene benefit most from the addition of temozolomide.[11] In glioblastoma patients who have received standard radio-chemotherapy, the combination of maintenance temozolomide plus low-intensity alternating electric fields, which are delivered to the tumor through a portable medical device that is applied to the scalp, can improve progression-free survival and overall survival compared with maintenance temozolomide alone.[A1] The addition of bevacizumab, a monoclonal antibody that blocks vascular endothelial growth factor (VEGF), can be helpful to control cerebral edema, but it does not prolong survival and is not recommended for routine use in patients with newly diagnosed glioblastoma.

In almost all patients, the glioblastoma recurs following initial therapy. Recurrences can be treated with reoperation, stereotactic radiosurgery, tumor-treating fields, systemic agents, or a combination of approaches.[A2] Commonly used systemic therapies include temozolomide rechallenge, bevacizumab, and lomustine (alone or in combination with procarbazine and vincristine) under expert supervision.[12] A second course of radiation with concurrent bevacizumab is generally well tolerated and can prolong disease control.[A3] Chemotherapy is generally well tolerated and associated with minimal toxicity. Elderly patients, however, often do poorly, so alternative treatment approaches may be preferable. Since none of the currently available treatment approaches have been proven to prolong survival in recurrent glioblastoma, patients with recurrent glioblastoma should be encouraged to participate in a clinical trial whenever possible.

The median overall survival time for patients with glioblastoma is about 15 months. Key prognostic factors include patient age and performance status, as well as the presence or absence of *IDH* gene mutation and O6-methylguanine-DNA methyltransferase promoter methylation.

Astrocytomas, IDH Wildtype, Grade 2/3

No large randomized data exist to guide treatment decisions for patients with IDH-wildtype astrocytomas. Immediate postoperative radiation and chemotherapy, as described for the treatment of glioblastoma, are often used. However, close observation may be appropriate for young patients whose grade 2 tumors have undergone gross total resection.

Astrocytomas, IDH-Mutant, and All Oligodendrogliomas

For IDH-mutant astrocytomas and oligodendroglial tumors, resection should be performed at diagnosis. If a complete resection is achieved and the patient is younger than age 40 years, these patients have an excellent prognosis and may be followed with serial imaging alone to avoid long-term neurotoxicity from cranial irradiation.

For incompletely resected grade 2 tumors and for all grade 3 tumors, regardless of the degree of resection, however, immediate postoperative radiation plus adjuvant chemotherapy is recommended.[13] Postoperative radiation with adjuvant temozolomide is recommended for IDH-mutant astrocytomas.[A4] The combination of radiotherapy and chemotherapy with procarbazine, lomustine, and vincristine is superior to radiotherapy alone for patients with anaplastic oligodendroglial tumors.[A5]

Treatment is also instituted immediately after initial surgery in patients who have progressive neurologic symptoms or intractable seizures. It is also given at recurrence, sometimes following re-resection. Grade 2 tumors can transform to a higher-grade malignant neoplasm, a change that typically is associated with the appearance of contrast enhancement on MRI. Resection or a biopsy may be necessary in these patients to establish a change in grade, which often determines the appropriate dose of radiotherapy (60 Gy for high-grade lesions and about 54 Gy for low-grade tumors). Re-resection is followed by radiation therapy plus chemotherapy if patients have not received it previously. Salvage regimens include lomustine alone, bevacizumab, temozolomide (150 to 200 mg/m^2 for 5 days every 4 weeks for anywhere from 6 to 24 cycles), and carboplatin under expert supervision.

Optic and Brain Stem Glioma

Optic gliomas, which can involve the optic nerve or optic chiasm, are usually associated with neurofibromatosis type 1 (Chapter 385). Optic gliomas are typically pilocytic tumors that can have an indolent course, including rare spontaneous regression. Optic gliomas often are not amenable to surgical resection, and they can have a stuttering clinical course, with periods of visual loss punctuated by prolonged periods of visual stability. When necessary, radiation therapy or even chemotherapy may be useful under expert supervision, but often no treatment is required.

Brain stem gliomas usually involve the pons and less often the medulla or midbrain. Brain stem gliomas are most commonly seen in children in the first decade of life but can be found even in elderly people. Brain stem gliomas can have a low-grade or high-grade histology, but outcome is primarily determined by the location of the tumor. In general, most brain stem gliomas have a dismal

outcome, with survival of 1 year or less, but relatively benign variants occasionally occur, especially in adults with tumors in the medulla or midbrain.

Medulloblastoma

Medulloblastomas usually occur in the vermis of the cerebellum and principally affect children and young adults. Boys outnumber girls by about 2 : 1, and peak onset is age 7 years. Medulloblastoma in postpubertal patients and adults is rare and usually affects the cerebellar hemisphere.

Transcription profiles have identified four distinct subclasses that include the Wnt subtype (10% of tumors) driven by a stabilizing mutation in *CTNNB1* (β-catenin), which has an excellent prognosis; the SHH subtype (30% of tumors) with mutations in *PTCH1, SMO, GLI2,* or *SUFU,* which has an intermediate prognosis; group 3 (25% of tumors), which has an increased expression of *MYC* and has the worst prognosis; and group 4 (35% of tumors), which is characterized by isochromosome 17q and marked male predominance.[14] Medulloblastomas have a characteristic clinical presentation, with ataxia (due to cerebellar and brain stem involvement), headache, nausea, and vomiting (due to increased intracranial pressure from obstructive hydrocephalus).

TREATMENT AND PROGNOSIS

Aggressive surgery with complete excision is strongly associated with improved outcome. Surgery is always followed by craniospinal radiation therapy.

Adults with medulloblastoma should receive adjuvant multiagent chemoradiotherapy (e.g., vincristine, lomustine or cyclophosphamide, and cisplatin) under expert supervision. This treatment is associated with 5-year overall survival rates of up to 70% in adults with medulloblastoma despite its considerable toxicity.

Whether molecular subclasses should supersede clinical stratification or dictate the selection of treatment is unknown. The SHH-driven tumors may respond to Smo inhibitors.

Therapy of medulloblastoma often results in delayed complications in survivors, including intellectual deficits, growth impairment, and endocrinologic dysfunction. Late relapses and secondary neoplasms compromise long-term outcome.

Ganglioglioma

Gangliogliomas possess both a glial component and a neoplastic neural component (ganglion cell). Some low-grade gangliogliomas are indolent and do not require additional treatment after surgical extirpation. Patients with anaplastic tumors may fare better than patients with malignant gliomas, but recurrence is the rule despite surgery and radiation therapy. Gangliogliomas and other circumscribed astrocytic gliomas, glioneuronal, and neuronal tumors frequently harbor somatic mutations in the *BRAF* gene and respond to inhibitors of the RAF-MEK signaling axis.[15]

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Primary CNS lymphomas are associated with immunodeficiency states, particularly acquired immunodeficiency syndrome and organ transplantation, and are seen with increased frequency among the apparently immunocompetent population, in whom the median age at diagnosis is about 60 years. These tumors are usually diffuse large B-cell non-Hodgkin lymphomas identical to systemic diffuse large B-cell lymphoma (Chapter 171).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The tumor can involve the cerebrospinal fluid, eye, and brain, where it is multifocal in about 40% of patients at presentation (Fig. 175-6). Biopsy is usually the preferred surgical approach.

TREATMENT

In contrast to all other brain tumors, surgical resection may not be associated with improved survival and can cause significant neurologic morbidity. Chemotherapy is the primary treatment, and high-dose methotrexate (3 to 8 g/m^2 on alternate weeks for 3 to 12 months) is the most important chemotherapeutic agent.[16] In most patients, radiation therapy is avoided because the necessary whole brain irradiation causes significant cognitive impairment when it is combined with chemotherapy and does not prolong survival. Corticosteroids (e.g., dexamethasone 8 to 16 mg/day), which are frequently used as part of the chemotherapeutic regimen, not only help manage the associated cerebral edema but also can cause tumor regression. Ibrutinib, which is an inhibitor of Bruton tyrosine kinase, has antitumor activity in recurrent or refractory primary CNS lymphoma.

With the use of multiagent chemotherapy, with or without cranial irradiation, median survival is 3 to 5 years. Younger patients who receive high-dose chemotherapy and autologous stem cell transplantation may have a 60 to 70% chance of cure.[A6]

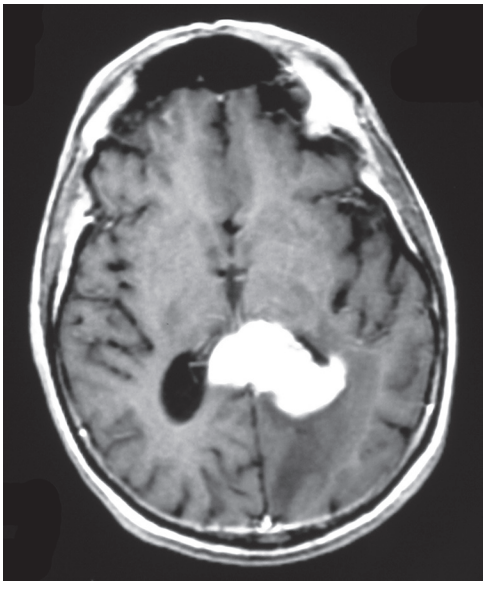

FIGURE 175-6. Primary central nervous system (CNS) lymphoma. A post-gadolinium magnetic resonance image demonstrating a diffusely enhancing splenial lesion. The periventricular location and absence of central necrosis are characteristic of primary CNS lymphoma.

OTHER INTRA-AXIAL PRIMARY BRAIN TUMORS

Rare, intra-axial cerebral tumors include ependymomas, which are optimally treated with surgical excision followed by radiation therapy.[17] Choroid plexus papillomas and carcinomas may be manifested with hydrocephalus or lateralizing signs. Resection may be sufficient for benign papillomas, but carcinomas rapidly recur even when postoperative radiation therapy is also used. Colloid cysts of the third ventricle are benign tumors that can cause obstructive hydrocephalus; they may be treated with a third ventriculostomy or with resection by use of an intraventricular endoscope.

Hemangioblastomas occur primarily in the cerebellum but can also occur in the spinal cord and the hemispheres. About 15% of patients with a hemangioblastoma have the autosomal dominant disorder von Hippel-Lindau disease (Chapter 385), which is characterized by hemangioblastomas in the CNS and retina, renal cell carcinoma, pheochromocytoma, endolymphatic sac tumors, and cysts in a variety of visceral organs. Hemangioblastomas are treated by surgical excision and require radiation therapy only for recurrence. Complete removal usually results in cure. The HIF-2α inhibitor belzutifan has shown promising antitumor activity against CNS hemangioblastomas in patients with von Hippel-Lindau disease.[18]

BRAIN METASTASIS

EPIDEMIOLOGY

Metastases are the most common intracranial tumors in adults. Every systemic cancer is capable of metastasizing to the brain. Melanoma (Chapter 188) has the greatest propensity to spread to the CNS, but the most common causes of CNS metastases are cancers of the lung (Chapter 177) and breast (Chapter 183). CNS metastases are being seen with greater frequency because patients with systemic cancers have prolonged survival with better treatments. In most patients with brain metastases, CNS disease develops late in the course of their illness, but a brain metastasis may be the initial presentation of a systemic cancer. In most of these patients, lung cancer is the primary site; in some, however, a primary site is never identified (Chapter 164).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with brain metastases present with progressive neurologic symptoms and signs that typically include headache, seizures, and lateralizing signs. Metastases are best diagnosed by cranial MRI with gadolinium (Fig. 175-7). All lesions can be clearly seen by MRI, which is better than CT for visualizing the posterior fossa. Metastases, which are usually well-circumscribed lesions at the gray matter–white matter junction, are often associated with extensive edema. Hemorrhage into a metastasis occurs most frequently with metastases from melanoma, renal cancer, or thyroid cancer. Because brain metastases from lung cancer are so common, however, they are the most common hemorrhagic type. Sometimes, hemorrhage into a brain metastasis is best visualized by noncontrast head CT.

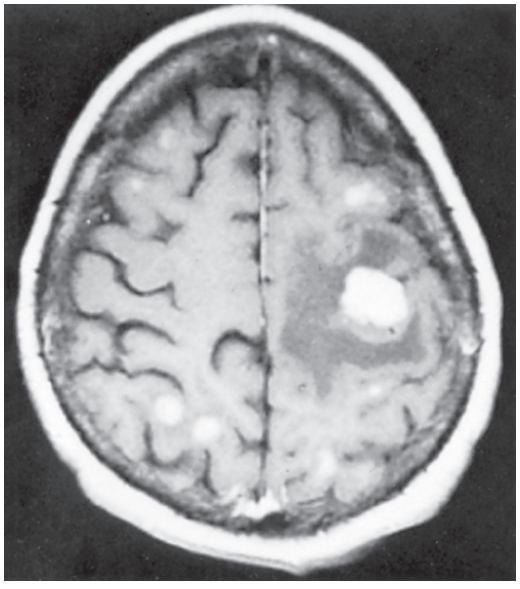

FIGURE 175-7. Brain metastasis. Multiple metastases from breast carcinoma are seen on this T1-weighted gadolinium-enhanced magnetic resonance image. The multiple smaller tumors were not visible on computed tomography, even after a contrast agent was given.

TREATMENT

The survival of patients with brain metastasis has been improved in recent decades by the increasingly individualized refinement of radiosurgical techniques and the development of more effective systemic therapies. Corticosteroids, especially dexamethasone (8 to 12 mg daily), are useful for symptomatic brain metastases. Anticonvulsant medications (Table 372-6) are required in patients who have seizures but are not recommended prophylactically in patients without seizures.[19]

Surgery

Because brain metastases do not widely infiltrate into brain tissue and tend to have a pseudo-capsule around them, they can be completely excised surgically. Complete removal of a single brain metastasis can substantially prolong life and maintain neurologic function. If multiple lesions can be completely resected, these patients do as well as patients in whom a single lesion has been removed.

Radiation Therapy

Postoperative whole brain radiation therapy significantly improves control of CNS disease after resection of a single brain metastasis, but it does not prolong survival because patients die of progressive systemic tumor.[20] The use of postoperative whole brain radiation therapy is frequently decided on an individual basis, but increasingly partial brain radiotherapy or stereotactic radiosurgery to the postoperative bed are used instead to avoid irradiating the entire brain. Nonetheless, many patients with multiple brain metastases are best treated with a course of whole brain radiation therapy, most commonly 3 Gy in 10 fractions for a total of 30 Gy. Stereotactic radiosurgery, with either a gamma knife that delivers gamma radiation from multiple cobalt sources or a linear accelerator that delivers x-rays to a highly focused area involving the tumor, has been effective for the treatment of patients with one to three brain metastases, resulting in less cognitive deterioration at 3 months, with no difference in overall survival compared with whole brain radiotherapy.[A7,A8] Growing evidence suggests the use of stereotactic radiosurgery for as many as 10 brain metastases.

Most patients tolerate radiosurgery without difficulty, but the procedure is occasionally complicated by seizures or acute swelling that causes more neurologic dysfunction. Approximately 20 to 30% of patients develop radiation necrosis, which may be indistinguishable clinically and on MRI from recurrent tumor. One advantage of stereotactic radiosurgery is that most of the normal brain is not exposed to the radiation.

Systemic Therapy

Chemotherapy is used to treat brain metastases from highly chemosensitive primary cancers, such as testicular cancer (Chapter 185), small cell lung cancer (Chapter 177), and, to a lesser extent, breast cancer (Chapter 183). Bevacizumab under expert supervision can be effective in progressive brain metastases or radionecrosis after stereotactic radiosurgery. Chemotherapy also has increasingly been used in asymptomatic patients in whom brain metastases are identified at diagnosis on a screening MRI examination and who require chemotherapy for their systemic disease. Brain metastases will frequently respond in a fashion comparable to other systemic sites of disease.

The choice of agents is based on the primary type of cancer and the patient's prior drug exposures under expert supervision. For patients with *BRAF*-mutant melanoma (Chapter 188), for example, the combination of BRAF plus MEK inhibition (dabrafenib plus trametinib) can achieve intracranial responses.[21] Similarly, systemic immunotherapy with nivolumab plus ipilimumab can provide clinically meaningful intracranial activity against asymptomatic melanoma brain metastases.[A9] Upfront systemic therapy with the combination of the HER2 kinase inhibitor tucatinib, capecitabine, and trastuzumab can be considered for the treatment of asymptomatic brain metastases in HER2-positive metastatic brain cancer patients (Chapter 183) who were previously treated with trastuzumab, pertuzumab, and trastuzumab-emtansine (T-DM1).[A10] Systemic therapy with newer-generation CNS-penetrant tyrosine kinase inhibitors, rather than radiation or surgery, is increasingly used for the initial treatment of lung cancer patients (Chapter 177) whose tumors harbor EGFR mutations, anaplastic lymphoma kinase (ALK) translocations, c-ROS oncogene 1 (ROS1)-rearrangements, RET fusions, or MET exon-14-skipping mutations.

FIGURE 175-8. Leptomeningeal metastases. Gadolinium-enhanced magnetic resonance imaging of the lumbosacral spine in a patient with leptomeningeal metastases from melanoma. Multiple enhancing nodules are seen on the cauda equina, and the conus medullaris and lower spinal cord are encased by tumor.

INTRACRANIAL LEPTOMENINGEAL METASTASIS

The brain is the most common intracranial site of metastases, but systemic cancer can spread to the dura and the leptomeninges as well. Dural metastases most commonly arise from breast (Chapter 183) or prostate (Chapter 186) cancer, frequently from a metastasis in the overlying calvaria.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Metastasis to the leptomeninges is often manifested as multifocal neurologic symptoms and signs. These metastases involve the cranial nerves to cause diplopia or bulbar palsy (E-Fig. 175-1); the cervical and lumbar roots to cause limb pain or weakness; and the intracranial space to cause headache, nausea, vomiting, and elevated intracranial pressure. The diagnosis is established by the presence of tumor cells in the cerebrospinal fluid, by cytologic examination or novel techniques to identify isolated cancer cells, or by neuroimaging that definitively outlines tumor in the subarachnoid space (Fig. 175-8).

TREATMENT

Treatment frequently involves radiation therapy to symptomatic sites. Intrathecal chemotherapy, usually through an intraventricular cannula (Ommaya reservoir), or systemic chemotherapy with agents or doses that penetrate into the cerebrospinal fluid are also used under expert supervision.

FIGURE 175-9. Multilevel epidural spinal cord compression. This patient with metastatic breast cancer has multiple areas of ventral epidural tumor seen throughout the thoracic spine on this post-gadolinium sagittal magnetic resonance image.

SPINAL TUMORS

Spinal tumors can be categorized according to the anatomic area they involve: extradural, intradural extramedullary, and intramedullary (Table 175-5). Extradural tumors typically arise from the bone elements of the spine and cause neurologic symptoms and signs by compressing the spinal cord. Intradural but extramedullary tumors arise from the pachy-meninges or nerve roots (meningiomas or schwannomas) and can cause either radicular symptoms or spinal cord compression. Most intradural extramedullary tumors are benign. Intramedullary spinal cord tumors are rare; they arise from the spinal cord parenchyma and have a biology that is similar to the biology of brain tumors.

EXTRADURAL TUMORS

Most extradural tumors originate from a metastasis to the bone elements of the spine, typically the vertebral body and occasionally the vertebral lamina or spinous process. Expansile growth of the bone tumor impinges on the spinal canal and, if untreated, compresses the spinal cord or the nerve roots as they exit the intervertebral foramina. Whereas most of these lesions arise from bone metastases, extradural tumors can also arise from paravertebral metastases that can grow through the intervertebral foramina and into the epidural space without affecting surrounding bone structures. Very rarely, a direct metastasis to the epidural space is also seen. The most common primary cancers that cause extradural metastases are prostate cancer (Chapter 186), breast cancer (Chapter 183), lung cancer (Chapter 177), and the lymphomas (Chapters 171 and 172). Hematologic malignant neoplasms may be associated with paravertebral disease that grows through the intervertebral foramina. Less common are primary tumors of the spine, including chordomas, osteogenic sarcomas, plasmacytomas, and chondrosarcomas.

CLINICAL MANIFESTATIONS

Extradural tumors cause neurologic symptoms and signs by compressing the spinal cord. Although the mass is a primary bone tumor or a metastasis from a distant source, 98% of patients present with pain that is usually localized to the site of the tumor. Because the spine has more thoracic than cervical or lumbar vertebrae, the tumor and pain are likely to be in the middle or high back, a site that is a less common site for benign pain (Chapter 369). Back pain often precedes the development of any other neurologic symptom or sign, frequently by weeks and occasionally by months. Motor impairment and sensory symptoms are present in about 50% of patients, whereas sphincter disturbances are found in only about 25% of patients.

DIAGNOSIS

Severe back pain in a patient with cancer should be evaluated by MRI, which does not require intravenous administration of contrast material. Plain films of the spine, bone scans, or even CT scans may show bone disease, but epidural tumor can only be seen only on MRI (Fig. 175-9). Furthermore, MRI is the only technique that can reveal paravertebral or direct epidural metastasis. Patients who cannot have an MRI study should be imaged by CT with sagittal reconstruction images.

The differential diagnosis of extradural tumors includes epidural abscess (Chapter 382), acute or subacute epidural hematomas (Chapter 369), herniated intervertebral discs (Chapter 369), spondylosis (Chapter 369), epidural lipomatosis, and, rarely, extramedullary hematopoiesis. On occasion, a percutaneous needle biopsy or decompressive laminectomy is required to make a definitive diagnosis.

TREATMENT

Epidural metastases require immediate treatment because patients can develop acute and unpredictable neurologic deterioration resulting in paraplegia.[22] Patients should be started on high-dose corticosteroids (usually >20 mg of intravenous dexamethasone), which rapidly relieve pain and may contribute to neurologic recovery.

Surgery followed by postoperative radiation therapy is superior to radiation therapy alone for preserving the ability to walk and may prolong survival in a wide population of patients with metastatic spinal cord compression. However, it may not benefit patients who are age 65 years and older.

Stereotactic radiosurgery is also an effective option to treat epidural metastases, either initially or at the time of relapse.[A11] It is much easier to preserve neurologic function than to reverse impairment, so clinically silent areas of extradural tumor that are detected on MRI should be treated before neurologic compromise develops. Patients with epidural metastasis can have a good neurologic outcome if they are treated before the onset of severe neurologic compromise, but their overall survival is usually short because of the presence of widespread metastatic disease.

Patients whose primary tumor arises in the spine, such as an osteogenic sarcoma (Chapter 187), should undergo definitive surgery. The need for postoperative radiation therapy is based on the tumor's histology.

INTRADURAL EXTRAMEDULLARY TUMORS

MENINGIOMAS

Spinal meningiomas are benign, slow-growing tumors that occur primarily in middle-aged women and are predominantly located in the thoracic region.

Back pain is a common symptom, but about 25% of patients have no pain and present with slowly progressive neurologic dysfunction, typically a gait disorder that has been progressing, frequently for years. Spinal MRI with gadolinium clearly delineates the lesion. Surgical resection is curative, and a complete resection can usually be accomplished easily.

NERVE SHEATH TUMORS

Nerve sheath tumors include schwannomas and neurofibromas. Both typically arise from the dorsal root, and the first symptom is often radicular pain that precedes symptoms of spinal cord compression by months or even years. Some patients with spinal neurofibroma or schwannoma have neurofibromatosis type 1 (Chapter 385), but most do not. The diagnosis is clearly established by gadolinium-enhanced MRI of the spine. The treatment is surgical, and complete removal results in cure.

METASTASES

Metastasis to the spinal leptomeninges can be manifested as an intradural extramedullary lesion. A single large tumor nodule can cause focal symptoms and signs referable to that spinal level. In most patients, however, multiple levels of the neuraxis are involved, and patients have multifocal neurologic symptoms and signs. Cervical and lumbosacral radicular pain, as well as sensory and motor loss, are seen in more than half of patients. The diagnosis is established by gadolinium-enhanced MRI showing multifocal nodules or sometimes a layer of cells coating the spinal cord or nerve roots (see Fig. 175-9). If imaging is negative, the diagnosis can be established by demonstrating tumor cells in the cerebrospinal fluid.

TREATMENT

Because of the diffuse nature of the disease, surgery is not an option. Treatment is complicated and frequently requires radiation therapy to symptomatic sites of disease, intrathecal chemotherapy best administered through an intraventricular cannula (Ommaya device) and occasionally systemic chemotherapy under expert guidance. Radiation therapy can ameliorate neurologic symptoms, particularly pain, but the disease often has a relentless progressive course, and results in death in 3 to 6 months despite aggressive therapy.

INTRAMEDULLARY TUMORS

Intramedullary spinal cord tumors are similar to neoplasms that arise in brain parenchyma. The most common spinal cord tumors are ependymomas and astrocytomas. Hemangioblastomas (particularly in association with von Hippel-Lindau disease), lipomas, and, rarely, intramedullary metastases are also seen.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

All intramedullary tumors have a similar clinical presentation, and pain is a common initial symptom. Signs of spinal cord dysfunction subsequently ensue and reflect the location of the lesion. In addition, some intramedullary tumors are accompanied by a syrinx (Chapter 389), which can contribute to symptoms. The classic signs of intramedullary spinal cord lesions, such as dissociated sensory loss, sacral sparing, and early sphincter problems, are not sufficiently reliable to distinguish intramedullary from extramedullary lesions. The diagnosis is established by gadolinium-enhanced and T2-weighted MRI (Fig. 175-10).

TREATMENT

Surgery is the first therapeutic intervention, both to obtain a definitive diagnosis and to resect the lesion. Complete resection of spinal cord tumors is possible, particularly in the case of ependymomas and hemangioblastomas. However, spinal cord tumors are rare, and only neurosurgeons experienced in removal of this type of lesion should perform the procedure. High-grade gliomas and residual ependymomas should be treated with postoperative radiation therapy. Low-grade astrocytomas of the spinal cord can be treated with radiation therapy when the patient develops symptomatic neurologic impairment. Presymptomatic treatment does not prevent the development of impairment nor necessarily delay it. Intramedullary metastases do not require surgery because the diagnosis is usually straightforward. Radiation therapy provides limited benefit because these patients typically have other CNS metastases.

FIGURE 175-10. Spinal cord astrocytoma. T2-weighted sagittal magnetic resonance image demonstrating a lower cervical intramedullary low-grade astrocytoma; no enhancement was evident.

176 HEAD AND NECK CANCER

JULIE E. BAUMAN

DEFINITION

Head and neck cancer arises from the mucosal linings of the upper aerodigestive tract, sinonasal cavities of the face, major or minor salivary glands, or the structures of the base of skull including cranial nerves. The dominant histology, squamous cell carcinoma, comprises more than 95% of cancers of the oral cavity, pharynx, larynx, and paranasal sinuses (Fig. 176-1). Due to the sun-exposed cutaneous surface area of the scalp and face, nonmelanomatous skin cancers, in particular basal cell carcinoma and squamous cell carcinoma, are also frequent within the head and neck. Other less common neoplasms occurring within the anatomic structures of the head and neck include sarcoma as well as cutaneous or mucosal melanoma, which are treated according to the principles for these mesodermal malignancies (Chapters 187 and 188, respectively).

Oral Cavity

The margins of the oral cavity extend superiorly from the skin-vermillion border of the upper lip to the junction of the soft and hard palates, inferiorly from the skin-vermillion border of the lower lip to the circumvallate papillae, and laterally to the anterior tonsillar pillars. The structures of the oral cavity include the mucosal lip, buccal mucosa, upper and lower alveolar ridges, retromolar trigone, floor of the mouth, hard palate, and oral or mobile tongue.

Nasopharynx

The margins of the nasopharynx start anteriorly at the posterior choana and extend along the superior, posterior, and lateral walls to a theoretical plane between the free edge of the soft palate and the posterior pharyngeal wall. The structures of the nasopharynx include the fossae of Rosenmüller, the superior surface of the soft palate, and the mucosal linings of the eustachian tube and choanal orifices.

Oropharynx

The margins of the oropharynx extend from the plane of the superior surface of the soft palate to the superior surface of the vallecula, or hyoid bone. The structures of the oropharynx include the base of the tongue (the lingular tonsil), the palatine tonsils, the glossotonsillar sulcus, the inferior surface of the soft palate and uvula, the anterior and posterior tonsillar pillars, and the continuity of the lateral and posterior pharyngeal walls. Oropharyngeal squamous cell carcinoma largely arises from the rich lymphoreticular tissue of the lingular and palatine tonsils.

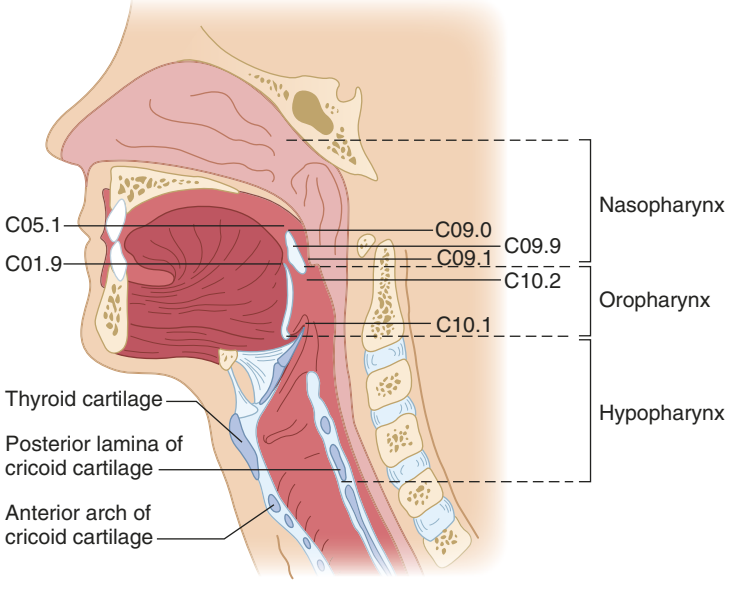

FIGURE 176-1. More than 95% of head and neck cancers arise from the mucosal surfaces of the upper aerodigestive tract. Specific anatomic sites are associated with unique etiologies, including environmental and viral risk factors, and underpin modern staging systems and treatment paradigms.

Hypopharynx

The margins of the hypopharynx extend from the plane of the superior border of the vallecula to the plane of the lower border of the cricoid cartilage. The structures of the hypopharynx include the pyriform sinuses, the lateral and posterior hypopharyngeal walls, and the postcricoid region.

Larynx

The margins of the larynx include anteriorly the anterior surface of the epiglottis, the thyroid cartilage, and the anterior arch of the cricoid cartilage; posterolaterally the aryepiglottic folds and arytenoids; superolaterally the tip and lateral borders of the epiglottis; and inferiorly the plane of the inferior border of the cricoid cartilage. The structures of the larynx include the epiglottis and false cords (supraglottic larynx), the true vocal cords (glottis), and the subglottis.

Salivary Glands

The salivary glands of the head and neck comprise the major salivary glands, which include the parotid, submandibular, and sublingual glands, as well as the minor salivary glands, which are scattered throughout the lining of paranasal sinuses, oral cavity, pharynx, and larynx. Approximately 6 to 8% of head and neck cancers arise from the salivary glands. Although the unified biologic function of salivary glands is the production and secretion of saliva, salivary gland tumors are histologically, genetically, and prognostically diverse. The three most common histologies are mucoepidermoid carcinoma, adenoid cystic carcinoma, and salivary duct carcinoma, which presents de novo or arises from a preexisting pleomorphic adenoma.

EPIDEMIOLOGY

Head and neck cancer is the seventh most common incident cancer worldwide. Among the more than 900,000 index cases of head and neck squamous cell carcinoma estimated in 2020, the substantial majority was caused by environmental carcinogenesis.[1]

Viruses

Human Papillomavirus

Oropharyngeal squamous cell carcinomas also can be caused by oncogenic human papillomaviruses (HPVs). Oral HPV 16 infection (Chapter 344) is responsible for about 80% of oropharyngeal cancers in the United States and is the cause of the ongoing epidemic of oropharyngeal squamous cell carcinoma predominantly occurring in males across all inhabited continents. Patients who are diagnosed with HPV-associated oropharyngeal squamous cell carcinoma have a lower median age at diagnosis, 58 years, than patients with environmental head and neck squamous cell carcinoma. The male:female incidence ratio is approximately 5 : 1.

Oral HPV infection is sexually transmitted and consistently associated with oral sexual behavior, including oral-oral, oral-genital, and oral-anal exposures. The prevalence of oral oncogenic HPV infection has two distinct peaks among males: between ages 25 and 30 years and 55 and 60 years, whereas the median age at diagnosis of HPV-associated oropharyngeal squamous cell carcinoma is 58 years. Thus, the estimated latency period between initial oral HPV infection and the development of oropharyngeal squamous cell carcinoma is approximately 10 to 30 years.

In the United States, the proportion of oropharyngeal squamous cell carcinoma cases infected with HPV has increased substantially. Furthermore, the incidence of human papillomavirus–associated oropharyngeal squamous cell carcinoma in the United States surpassed the incidence of cervical cancer in 2016. Incidence rates of HPV-associated oropharyngeal squamous cell carcinoma also have been rising in Europe, Australia, Asia, Brazil, and Peru, although large regional, racial, and ethnic variations exist as demonstrated by lower rates in Central Europe, some regions of Latin America, and among Blacks and Hispanics in the United States.

Epstein-Barr Virus

The dominant risk factor for nasopharyngeal carcinoma is infection with the Epstein-Barr virus (Chapter 348), which is an endemic cause of nasopharyngeal carcinoma in Southeast Asia, North Africa, and circumpolar indigenous populations, where the median age of diagnosis is age 50 years.[2] Head and

ABSTRACT

Head and neck cancer, the seventh most common cancer worldwide, primarily arises from the mucosal linings of the upper aerodigestive tract. Head and neck squamous cell carcinoma, the dominant histology, is caused either by environmental carcinogens such as tobacco and alcohol or by oncogenic viruses including human papillomavirus (HPV) and Epstein-Barr virus (EBV). Chronic exposure to environmental carcinogens causes the accumulation of structural and functional DNA damage, thereby leading to HPV-negative head and neck squamous cell carcinoma. Persistent infection with oral HPV is now recognized as a necessary cause for the epidemic of oropharynx cancer in the United States and Western Europe, whereas EBV has long been recognized as the cause of endemic nasopharynx cancer in Southeast Asia. The clinician must be aware of the ongoing epidemic of HPV-associated head and neck squamous cell carcinoma when evaluating a new, painless neck mass. The diagnosis of head and neck squamous cell carcinoma is established by biopsy of the primary or fine-needle aspirate of the neck mass. For oropharynx primaries, HPV status is determined by p16 immunohistochemistry. More than 90% of head and neck squamous cell carcinoma cases are stage I to IVb and can be treated with curative intent. A specialized multidisciplinary team composed of surgical, medical, and radiation oncologists optimizes oncologic and functional outcomes. Important advances in minimally invasive transoral surgical techniques, intensity-modulated radiation therapy, and molecular- and immune-directed systemic therapies improve both survival and survivorship.

neck cancer related to the oncogenic Epstein-Barr virus is also predominantly observed in males, with a male:female incidence ratio of approximately 3 : 1.

Human Immunodeficiency Virus (HIV)

The age-standardized incidence of HPV-associated and HPV-negative head and neck squamous cell carcinoma is three-fold higher in HIV-infected individuals than in the general U.S. population. Although the excess in tobacco-related cancers is decreasing in this population, likely due to declining tobacco use, the excess of HPV-associated head and neck squamous cell carcinoma is increasing. Unlike cervical cancer, HPV-associated oropharyngeal squamous cell carcinoma is not considered an AIDS-defining cancer. Nonetheless, the prevalence of oral HPV infection in HIV-infected people is inversely related to the $CD4^+$ T-cell count, thereby indicating that HIV-induced immunosuppression and the associated failure to control oncogenic HPV are major contributors to rising incidence rates.

Environmental Carcinogens

The risk of environmental head and neck squamous cell carcinoma increases with age, with diagnosis at a median age of 66 years. Environmental risk factors can be proximal, when modifiable individual behavior causes direct carcinogen exposure from tobacco, alcohol,[3] or the areca nut (Chapter 165). Depending upon the world region, approximately half of attributable risk for head and neck cancer is explained by such proximal environmental risk factors. Distal environmental risk factors also pose a substantial burden in developing countries when unavoidable exposures to secondhand smoke, industrial pollution, pestilence, or war are especially associated with low socioeconomic status. Incidence patterns for head and neck cancer caused by environmental carcinogenesis vary in relationship to exposure patterns. In the populations of the United States, Hong Kong, and the Republic of Korea, for example, the incidence of environmental head and neck squamous cell carcinoma is declining in parallel to decreased overall use of tobacco, whereas the incidence is rising in Taiwan, England, and Peru.[4]

Occupational exposures associated with head and neck cancer include the group 1 human carcinogen solvents, polycyclic aromatic hydrocarbons, and heavy metals. For head and neck cancer, the strongest data point to formaldehyde for nasopharynx cancer, polycyclic aromatic hydrocarbons for larynx cancer, chlorinated solvents for all head and neck squamous cell carcinoma anatomic sites, and wood dust for sinonasal cancer.

Leukoplakia

The minority of oral squamous cell cancers are preceded by precancerous lesions, termed *oral potentially malignant disorders*. Acquired potentially malignant disorders, including *leukoplakia* (mucosal white patches or plaques that cannot be rubbed off) and *erythroplakia* (a fiery red patch that cannot be characterized clinically or pathologically as any other diagnosis; Chapter 393), are associated with the consumption of tobacco and alcohol.[5] The presence of loss of heterozygosity within an oral potentially malignant lesion is associated with higher risk of progression to oral cancer within the lesion itself or at another site within the carcinogen-exposed epithelium and is useful for risk stratification.[6]

Sex and Genetic Risk Factors

Males demonstrate a significantly higher risk than females for head and neck squamous cell carcinoma, whether caused by environmental carcinogens or oncogenic viruses. The male:female ratio for HPV-unrelated head and neck squamous cell carcinoma parallels the sex-specific prevalence of tobacco, alcohol, or areca nut use in any geographic area. For instance, the age-adjusted incidence rate of oral cavity cancer among men ranges from 1 to 16 per 100,000 population as compared with 0 to 10 per 100,000 among women. Despite a similar prevalence of anogenital HPV infection between adult males and females, males have significantly higher rates of oral HPV infection. In a population-based, cross-sectional study in the United States, 1.6% of men versus 0.3% of women harbored oral HPV 16. The disparity in HPV oral infection is reflected in the incidence rate of HPV-associated oropharyngeal squamous cell carcinoma, in which the male:female ratio ranges from 2.7 to 5.7. Plausible biologic explanations for this disparity are two-fold: oral HPV infections are cleared more slowly by males, and the linear dose-response relationship between lifetime number of sexual partners and the prevalence of oral HPV infection exists uniquely among males, thereby suggesting that males less frequently develop protective anti-HPV antibodies when exposed to anogenital HPV than do females.[7]

Genetically inherited disorders associated with oral leukoplakia and high risk of progression to head and neck squamous cell carcinoma include the rare bone marrow failure syndromes dyskeratosis congenita, which is caused by aberrant telomere biology, and Fanconi anemia, which is caused by inherited mutations in DNA repair genes (Chapter 151).

Dietary Factors

A reduced risk for head and neck squamous cell carcinoma has been associated with diets rich in fruits and vegetables, in particular the *Brassica* genus of cruciferous vegetables. Crucifers are rich in isothiocyanates, which are phytochemicals that potently induce cytoprotective enzymes that could mitigate the impact of environmental carcinogens including benzene, polycyclic aromatic hydrocarbons, and mutagenic aldehydes found in tobacco smoke and air pollution. People with incident environmental head and neck squamous cell carcinoma have lower serum levels of several micronutrients, including vitamin A and beta carotene, which may be surrogates for lower intake of fruits and vegetables.

Ionizing Radiation

Ionizing radiation was first recognized as a risk factor for both benign and malignant salivary gland tumors among long-term survivors of the Hiroshima and Nagasaki, Japan, atomic bombs. Increased odds of salivary gland tumors are also observed in people treated with therapeutic radiation during childhood, with evidence of a dose-response relationship. Unlike head and neck squamous cell carcinoma, salivary gland tumors are not associated with tobacco exposure, with the single exception of the benign Warthin tumor.

PATHOBIOLOGY

Environmental Carcinogenesis

The transformation of oral epithelial cells by environmental carcinogens is based on the principle of multistep carcinogenesis, in which the accumulation of structural and functional DNA damage drives stepwise clonal evolution. Loss of heterozygosity, also known as allelic imbalance, has been quantified across the histopathologic spectrum of hyperplasia, dysplasia, and carcinoma in situ to model malignant transformation. In essence, environmentally induced head and neck squamous cell carcinoma is characterized by loss of function of tumor suppressor genes and genes that influence NOTCH signaling.[8] A central, early molecular event is loss of heterozygosity at 9p21, which is the locus of the *CDKN2A* gene. *CDKN2A* encodes p16, which is a tumor suppressor that regulates cell cycle traversal from the G1 to S-phase. Mutation of *TP53* is a later molecular event. Mutations of *CDKN2A* and *TP53* are the most common genetic alterations in HPV-negative head and neck squamous cell carcinoma and are observed in 57% and 84% of cases, respectively. Moreover, expression of p16 is lost due to epigenetic silencing in an additional 30% of tumors, thereby leading to the histopathologic classification of HPV-negative head and neck squamous cell carcinoma as "p16-negative." *PIK3CA*, which encodes the alpha subunit of phosphoinositide-3-kinase (PI3K), is the most commonly mutated oncogene in HPV-negative head and neck squamous cell carcinoma.[9] Nongenomic activation of the oncogenes epidermal growth factor receptor (EGFR) and cyclooxygenase-2 (COX2) is induced by tobacco smoke and also increases during oral epithelial transformation. Aberrant activation of PI3K, EGFR, and COX2 contributes to uncontrolled cellular proliferation while subverting an appropriate apoptotic response to DNA damage.

Viral Carcinogenesis

HPV, which is a member of the *Papillomaviridae* family, is an epitheliotropic, double-stranded, circular DNA virus with more than 170 distinct genotypes (Chapter 344). The viral life cycle is strictly dependent upon the cellular differentiation program of the keratinocyte, and viral oncogene expression is coordinated with cellular division and stratification. Members of the alpha genus infect mucosa, and high-risk anogenital genotypes, including HPV 16 and 18, are the established cause of cervical cancer. HPV genotype 16 also has a predilection for the lymphoid-rich mucosa of the oropharynx, and it comprises more than 95% of DNA isolated from oropharyngeal squamous cell carcinoma specimens. In particular, the early genes, E6 and E7, are transcribed in the basal and parabasal cell layers. The E6 and E7 oncoproteins degrade two critical tumor suppressors, p53 and retinoblastoma, respectively. Retinoblastoma is a nuclear protein that serves as the major G1 checkpoint in cell cycle regulation. The functional loss of retinoblastoma and p53 permit unbridled cellular proliferation. As the keratinocyte stratifies into the spinous epithelium, late viral genes are expressed, including the L1 and L2 capsid proteins. Ultimately, progenitor virions are encapsidated and released from the anuclear, cornified keratinocytes. In an HPV-transformed malignancy, late viral

gene expression is lost, and the virus fails to complete its life cycle. However, the E6 and E7 oncoproteins are preserved and necessary for maintenance of the transformed phenotype.

The mutational spectrum of HPV-associated oropharyngeal squamous cell carcinoma is distinct from that of HPV-negative disease. Although p53 dysfunction appears to be a universal requirement for squamous epithelial transformation, in HPV-associated oropharyngeal squamous cell carcinoma, this dysfunction is accomplished by the degradation of p53 protein by the E6 oncoprotein. Thus, in HPV-infected cells there is little selective advantage for *TP53* mutations, which are rarely identified in this setting. Likewise, genomic alterations in *CDKN2A* are not observed. In fact, as a consequence of negative feedback inhibition, p16 is upregulated as E7 degrades retinoblastoma, resulting in the histopathologic classification of HPV-positive oropharyngeal squamous cell carcinoma as "p16-positive." Diffuse nuclear and cytoplasmic immunohistochemical (IHC) staining for p16 is an accepted surrogate for HPV in oropharyngeal squamous cell carcinoma. The most common genomic alteration in HPV-associated oropharyngeal squamous cell carcinoma, found in approximately 50% of cases, is mutation or amplification of the oncogene *PIK3CA*. The selection for gain-of-function alterations in *PIK3CA* results in hyperactive PI3K pathway signaling, and the associated pro-proliferative, antiapoptotic phenotype may initially enhance the viral life cycle.

Immunology

Whether caused by environmental carcinogens or HPV oncogenes, head and neck squamous cell carcinoma demonstrates a markedly suppressive immune profile. Although immunogenic tumor antigens exist in head and neck squamous cell carcinoma, as confirmed by circulating T lymphocytes specific for p53 and the E6/E7 oncoproteins, head and neck squamous cell carcinoma evades recognition by selective loss of human leukocyte antigen I as well as antigen processing machinery. Head and neck squamous cell carcinoma also induces a tumor-permissive cytokine profile, in which immunosuppressive cytokines such as TGF-β, interleukin-6, and vascular endothelial growth factor predominate over immune-stimulatory cytokines such as IFN-γ or interleukin-12. Head and neck squamous cell carcinoma also demonstrates critical defects in immune effector cells. Tumor-infiltrating lymphocytes demonstrate low expression of costimulatory T-cell receptors, such as OX40 and CD137, and high expression of coinhibitory receptors, including the immune checkpoints cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4) and programmed death 1 (PD-1).

Molecular Landscape of Salivary Gland Cancers

Approximately 90% of cases of mucoepidermoid carcinoma, which is the most common malignant salivary gland tumor, have the *MECT1-MAML2* gene fusion, which is now considered a genomic hallmark and used to establish pathologic diagnosis. Most adenoid cystic carcinomas harbor a gene rearrangement with the transcription factor *NFIB*, including *MYB-NFIB*, which is regulated by IGF1R in an AKT-dependent manner by overexpression of insulin growth factor receptor 1 (IGFR1). Secretory carcinoma, previously known as mammary analogue secretory carcinoma, is associated with *NTRK* gene fusions. Salivary duct carcinoma almost uniformly expresses the androgen receptor. Otherwise, salivary duct carcinoma demonstrates different genetic fingerprints depending upon whether it arises de novo or from a preexisting pleomorphic adenoma. De novo salivary ductal carcinoma frequently harbors somatic mutations in *HRAS, PIK3CA*, or both, whereas salivary ductal carcinoma from a preexisting pleomorphic adenoma is commonly enriched for HER2neu amplification.

CLINICAL MANIFESTATIONS

Oral Cavity Cancer

Proximal risk factors for oral cavity cancer include oral tobacco, tobacco smoke, areca nut (betel quid), alcohol, and poor dentition. Oral cavity cancers typically present at an early stage with the chief complaint of a persistent mouth sore, ulcer, or mass lesion.[10] Due to rich innervation, cancers of the mobile tongue are often painful and functionally interfere with the oral phase of eating. Dysarthria, but not hoarseness, can also be associated with larger lesions of the oral cavity.

HPV-Associated Oropharyngeal Squamous Cell Carcinoma

Risk factors for HPV-associated oropharyngeal squamous cell carcinoma include lifetime number of sexual partners and male sex. Although not pathognomonic, HPV-associated oropharyngeal squamous cell carcinoma typically presents with a small, asymptomatic T1-2 primary tumor and a persistent neck mass. Among squamous cell carcinomas of unknown primary metastatic to the cervical neck, the majority are p16-positive, and the primary is usually localized within the tonsil or base of the tongue. If an oropharynx tumor is more advanced, patients can present with globus sensation, throat pain, otalgia, dysphagia, odynophagia, or hemoptysis.

HPV-Unrelated Oropharyngeal Squamous Cell Carcinoma and Hypopharynx Cancer

Behavioral risk factors for HPV-unrelated oropharyngeal squamous cell carcinoma and hypopharynx cancer include tobacco smoke and alcohol. Due to occult anatomy, HPV-negative oropharynx and hypopharynx cancers often present with locally advanced T3-4 tumors that cause throat pain, dysphagia, or weight loss.

Larynx Cancer

Proximal risk factors for larynx cancer include tobacco smoking and alcohol use. Laryngeal cancers frequently present with hoarseness as early-stage T1-2 disease (Chapter 397). More advanced tumors can present with airway obstruction that requires emergent tracheostomy.

Nasopharyngeal Carcinoma

More than 70% of cases of nasopharyngeal carcinoma occur in Southeast Asia, although its incidence is declining worldwide. A painless cervical mass is the most common mode of presentation. Other associated symptoms include epistaxis, unilateral nasal obstruction, conductive hearing loss, and cranial nerve involvement.

Salivary Gland Tumors

Salivary gland tumors have a varied presentation depending upon the site of origin, with chief complaints including an uncomplicated parotid or submandibular mass, a new or growing oral or oropharyngeal lesion, dysphagia, cough, hoarseness, and even airway obstruction. A rare presentation is Bell palsy (Chapter 388) of cranial nerve VII, which courses through the deep parotid gland where occult tumors can be missed by routine inspection and palpation. The typical presentation of Bell palsy is acute, flaccid facial paralysis without an obvious parotid mass. If no mass is evident, cranial nerve VII palsy may initially be treated with steroids and antiviral therapy (Chapter 388), but follow-up for resolution is critical. An atypical presentation, such as a prodrome of unilateral facial twitching or spasm, slow progression over 1 month or more, or nonresolution after 4 months should trigger magnetic resonance imaging and referral to an otolaryngologist.

Other Head and Neck Tumors

Lymphomas frequently manifest either as neck nodes or in the lymphoid tissues of the ring of Waldeyer (Chapters 171 and 172). The tonsil is a preferred site for mantle cell and undifferentiated lymphomas. Solitary, extramedullary plasmacytoma (Chapter 173) can also occur in the nasopharynx or paranasal sinuses. Sarcomas (Chapter 187) in the head and neck include osteogenic sarcomas and nerve sheath tumors. Paragangliomas can be extensive, multicentric, and vascular. Rhabdomyosarcomas have a predilection for the orbit and sinuses. Melanomas and squamous cell cancers can be accompanied by neck adenopathy or parotid lesions.

DIAGNOSIS

Evaluation of a Neck Mass

In adults, particularly adults over age 40 years, a new neck mass requires a disciplined diagnostic approach with high suspicion for malignancy (Fig. 176-2). The mass, which can be a cystic mass, an enlarged lymph node, or a collection of lymph nodes (Chapter 154), should be considered cancer unless proved otherwise. In an adult male, HPV-associated oropharyngeal squamous cell carcinoma most commonly presents as a new painless neck mass. In endemic regions, Epstein-Barr virus–related nasopharyngeal carcinoma most commonly presents with a painless cervical neck mass, often in association with unilateral nasal obstruction and/or epistaxis. Supraclavicular masses usually are related to primary tumors below the clavicles, whereas submental, upper cervical, and midcervical neck masses almost always derive from head and neck tumors.

The differential diagnosis is framed by a detailed medical and social history, including assessment for time course; antecedent or current upper respiratory, dental, or sinus infection; epistaxis; dysphagia or odynophagia; otalgia; hoarseness; hemoptysis; B symptoms (fever, drenching night sweats, or weight loss); tobacco and alcohol habits; prior tobacco-related malignancy; prior

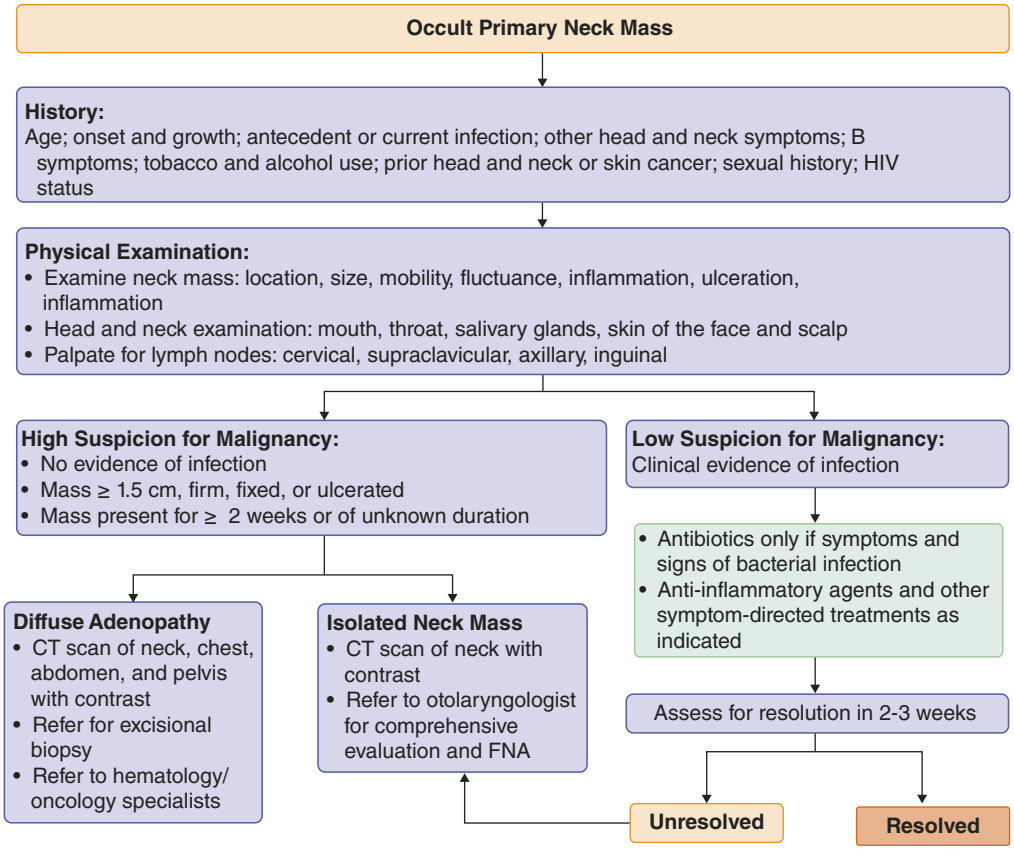

FIGURE 176-2. **Evaluation of an occult neck mass. B symptoms = fever, drenching night sweats, weight loss (>10% over 6 months); CT = computed tomography; FNA = fine needle aspiration; HIV = human immunodeficiency virus. (Adapted from Pynnonen MA, Gillespie MB, Roman B, et al. Clinical practice guideline: evaluation of the neck mass in adults. *Otolaryngol Head Neck Surg*. 2017;157[2 Suppl]:S1-S30.)**

skin cancer; sexual history; and HIV status. The physical examination should encompass the head and neck, including inspection and palpation of the oral cavity, oropharynx, and major salivary glands; inspection of the skin of the face and scalp; and a thorough examination of lymph nodes, including sites outside the neck.

The primary tumor site for an isolated upper cervical neck mass is most commonly found in the oropharynx (base of the tongue and tonsil), but salivary gland cancers, lymphomas, melanomas, and nonmelanoma skin cancers can also present in this manner. In East and Southeast Asia, a new neck mass also requires close examination of the nasopharynx.

Systemic symptoms or enlarged lymph nodes at other sites suggest lymphoma, whereas tenderness, warmth, and erythema suggest an infectious cause. Intraparotid nodes most commonly are metastases from skin malignancies. If the history and physical examination suggest reactive lymphadenopathy based on evidence of current or antecedent infection (Chapter 154), a brief course of observation or treatment with antimicrobial or anti-inflammatory medications is appropriate, but re-evaluation for resolution is critical. In all cases, a neck mass that persists for more than 3 weeks in an adult should prompt referral to an otolaryngologist to evaluate the patient for a potential malignancy.

Pathology

In the evaluation of a persistent neck mass, the initial test should be a fine needle aspiration (FNA) of the mass. Excisional biopsy is reserved for cases in which initial or repeat FNA is nondiagnostic and panendoscopy has identified no primary or when the baseline suspicion for lymphoma is very high due to extensive adenopathy outside of the neck (Chapter 154).

Ultimately, cytology or histology must confirm the diagnosis of head and neck squamous cell carcinoma. Environmental head and neck squamous cell carcinoma is associated with well to poorly differentiated cells, whereas well-differentiated tumors demonstrate unique features of keratinization including the presence of "keratin pearls" (Fig. 176-3 A and B). HPV-associated oropharyngeal squamous cell carcinoma is commonly associated with poorly differentiated or basaloid histology and lacks keratin pearls (Fig. 176-3 C and D). For oropharyngeal or unknown primary tumors, HPV status must be determined because it influences both staging and prognosis. The most widely used and accepted standard is immunohistochemistry for the cell cycle protein p16; diffuse nuclear and cytoplasmic staining in more than 70% of tumor cells signifies an HPV-positive tumor (Fig. 176-3E). Of note, p16 immunohistochemistry is not a direct measurement of the HPV 16 virus or its oncoproteins; rather, p16 overexpression confirms the presence of functionally relevant E7 oncoprotein. As such, p16 immunohistochemistry is not considered a surrogate for HPV infection outside of the oropharynx. Alternative methods for establishing the HPV status of oropharyngeal squamous cell carcinoma include in situ hybridization for HPV 16 DNA, multiplex polymerase chain reaction (PCR) for high-risk HPV genotypes, and detection of E6 and E7 mRNA by reverse transcription PCR.

Staging

Once a pathologic diagnosis of head and neck squamous cell carcinoma is established, the staging evaluation includes the following procedures:

- Complete head and neck examination with mirror or fiberoptic examination of the oropharynx, hypopharynx, larynx, and nasopharynx as indicated.
- Head and neck imaging. Locoregional staging is accomplished by a computed tomography (CT) or magnetic resonance imaging (MRI) scan of the primary and neck.
- Chest imaging. Less than 10% of patients with head and neck squamous cell carcinoma present with distant metastatic disease at diagnosis; however, distant metastases, when present, typically occur in the lungs. As a result, a diagnostic chest CT scan is a recommended component of staging; combined positron emission tomography (PET)/CT may also be considered, particularly in patients who have locally advanced tumors or nodal disease. Since patients with tobacco-related head and neck squamous cell carcinoma have a high risk for a second primary upper aerodigestive malignancy, including a head and neck, esophageal, or lung primary, a chest CT or PET/CT is also routinely indicated in such patients.
- The utility of panendoscopy under anesthesia with direct laryngoscopy, esophagoscopy, and bronchoscopy depends on expert consultation.

Each head and neck squamous cell carcinoma primary site has a staging system (Table 176-1). Staging for oral cavity tumors incorporates depth of invasion, tumor size, and invasion of adjacent structures. p16-positive (HPV-associated) oropharyngeal squamous cell carcinoma is distinguished from p16-negative oropharyngeal squamous cell carcinoma by a separate TNM staging system. p16-negative oropharyngeal squamous cell carcinoma is

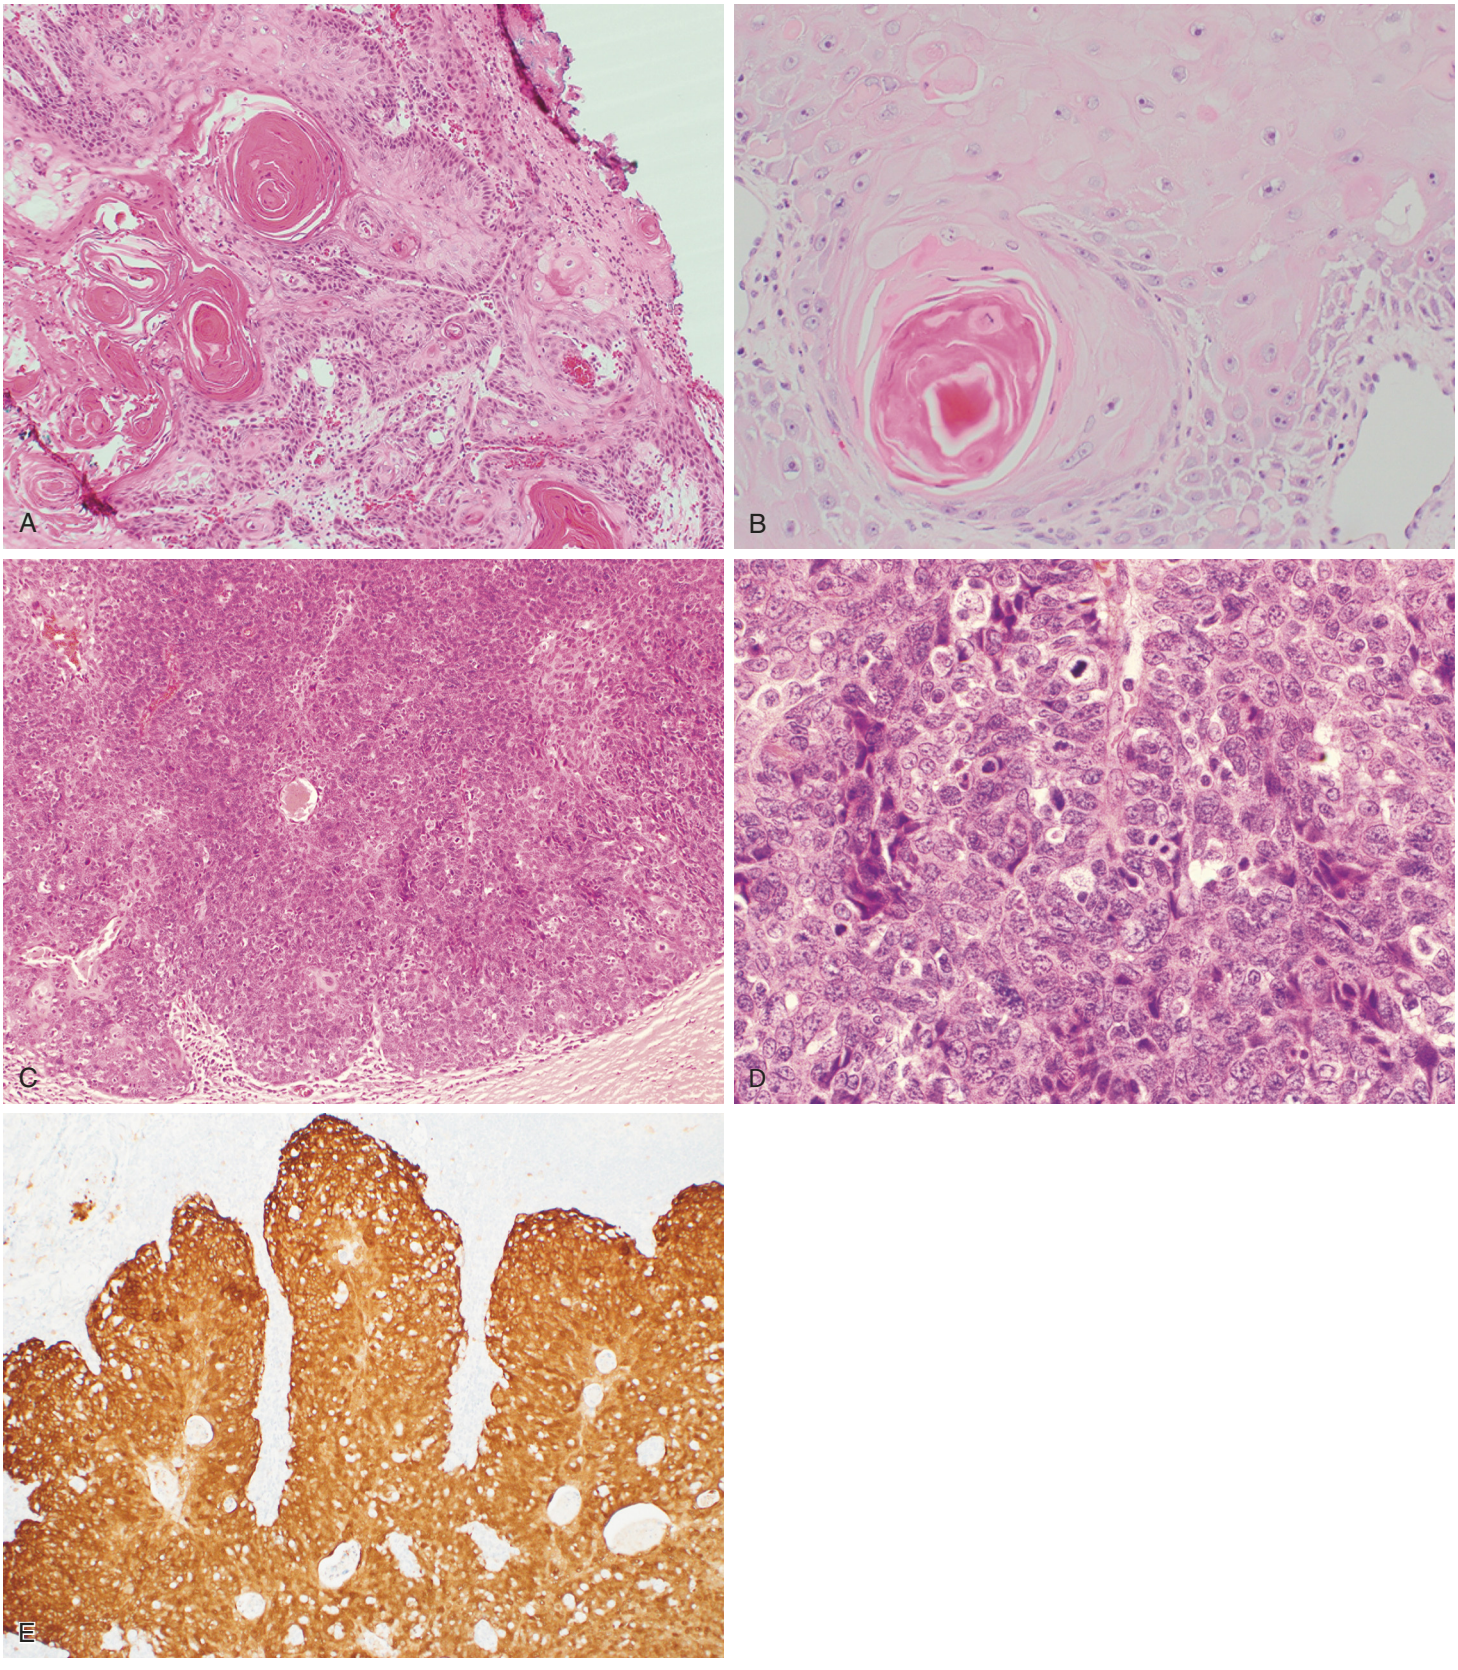

FIGURE 176-3. Head and neck squamous cell carcinoma histology and immunohistochemistry. A, The jagged outlines of well-differentiated squamous cell carcinoma tongues are associated with stromal desmoplastic reaction (low power). **B,** Keratin pearls, abnormal squamous cells forming concentric layers, are associated with well-differentiated squamous cell carcinoma (high power). **C,** Basaloid squamous cell carcinoma is frequently associated with human papillomavirus (HPV) infection, here demonstrating a highly infiltrative pattern of nests composed of poorly differentiated cells with pushing borders (low power). **D,** The basaloid squamous cell carcinoma cells demonstrate high nuclear to cytoplasmic ratios and numerous mitotic figures (high power). **E,** HPV-associated oropharyngeal squamous cell carcinoma shows poorly differentiated histology and diffuse nuclear and cytoplasmic staining for the p16 protein (high power).

grouped with hypopharynx cancers owing to the common etiology of environmental carcinogenesis, contiguous anatomy, and similarly poor prognosis. For hypopharynx and p16-negative oropharyngeal squamous cell carcinoma, tumor staging incorporates both size and invasion of adjacent structures. Staging of larynx cancer uniquely includes vocal cord mobility, where vocal cord fixation constitutes a T3 tumor irrespective of size. Due to distinct biology, patterns of spread, and natural history, nasopharyngeal carcinoma has its own staging system.

TABLE 176-1 CLINICAL PRIMARY TUMOR STAGING SYSTEM FOR HEAD AND NECK SQUAMOUS CELL CARCINOMA

TUMOR	LARYNX	LIP & ORAL CAVITY	HYPOPHARYNX	OROPHARYNX (p16-NEGATIVE)	OROPHARYNX (p16-POSITIVE)
T0	NA	NA	NA	NA	No primary identified
TX	Primary tumor cannot be assessed	Primary tumor cannot be assessed	Primary tumor cannot be assessed	Primary tumor cannot be assessed	NA
Tis	Carcinoma in situ	Carcinoma in situ	Carcinoma in situ	Carcinoma in situ	NA
T1	*Supraglottis*: Tumor limited to one subsite of supraglottis with normal vocal cord mobility *Subglottis*: Tumor limited to the subglottis *Glottis*: Tumor limited to the vocal cord(s) (may involve anterior or posterior commissure) with normal mobility	Tumor ≤2 cm, ≤5 mm depth of invasion (DOI) Note: DOI is depth of invasion and not tumor thickness	Tumor limited to one subsite of hypopharynx and/or ≤2 cm	Tumor ≤2 cm	Tumor ≤2 cm
T1a	*Glottis*: Tumor limited to one vocal cord				
T1b	*Glottis*: Tumor involves both vocal cords				
T2	*Supraglottis*: Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx *Subglottis*: Tumor extends to vocal cord(s) with normal or impaired mobility *Glottis*: Tumor extends to supraglottis and/or subglottis, and/or with impaired vocal cord mobility	Tumor ≤2 cm, DOI >5 mm and ≤10 mm *or* tumor >2 cm but ≤4 cm, and ≤10 mm DOI	Tumor invades more than one subsite of hypopharynx or an adjacent site, or >2 cm but ≤4 cm without fixation of hemilarynx	Tumor >2 cm but ≤4 cm	Tumor >2 cm but ≤4 cm
T3	*Supraglottis*: Tumor limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, preepiglottic space, paraglottic space, and/or inner cortex of thyroid cartilage *Subglottis*: Tumor limited to larynx with vocal cord fixation and/or invasion of paraglottic space and/or inner cortex of the thyroid cartilage *Glottis*: Tumor limited to the larynx with vocal cord fixation and/or invasion of paraglottic space and/or inner cortex of the thyroid cartilage	Tumor >4 cm *or* any tumor >10 mm DOI	Tumor >4 cm in greatest dimension or with fixation of hemilarynx or extension to esophagus	Tumor >4 cm or extension to lingual surface of epiglottis	Tumor >4 cm or extension to lingual surface of epiglottis
T4	Moderately advanced or very advanced	Moderately advanced or very advanced local disease	Moderately advanced or very advanced local disease	Moderately advanced or very advanced local disease	Moderately advanced local disease Tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible or beyond Note: Mucosal extension to lingual surface of epiglottis from primary tumors of the base of the tongue and vallecula does not constitute invasion of the larynx
T4a	*Supraglottis*: Moderately advanced local disease. Tumor invades through the outer cortex of the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus) *Subglottis*: Moderately advanced local disease. Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, straps muscle, thyroid, or esophagus) *Glottis*: Moderately advanced local disease. Tumor invades through the outer cortex of the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, cricoid cartilage, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)	*Lip*: Tumor invades through cortical bone or involves the inferior alveolar nerve, floor of mouth, or skin of face (i.e., chin or nose) *Oral cavity*: Tumor invades adjacent structures only (e.g., through cortical bone of the mandible or maxilla, or involves the maxillary sinus or skin of the face) Note: Superficial erosion of bone/tooth socket (alone) by a gingival primary is not sufficient to classify a tumor as T4	Tumor invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, or central compartment soft tissue Note: Central compartment soft tissue includes prelaryngeal strap muscles and subcutaneous fat	Tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible Note: Mucosal extension to lingual surface of epiglottis from primary tumors of the base of the tongue and vallecula does not constitute invasion of the larynx

TREATMENT

Multidisciplinary Team

In head and neck squamous cell carcinoma, both the cancer itself and its treatment place patients at risk for acute and long-term compromise of critical human functions, including speaking, eating, and breathing. Treatment by a multidisciplinary team composed of a surgical, medical, and radiation oncologist with specific expertise in head and neck cancer optimizes both oncologic and functional outcomes. Early consultation with specialists in dental sciences, nutrition, and speech and language pathology is also optimal. Given the social and behavioral risk factors associated with HPV-negative head and neck squamous cell carcinoma, the integration of patient navigators, social workers, and behavioral medicine specialists into the clinical management team can be particularly beneficial for addressing social isolation, transportation barriers, housing and food security, treatment compliance, and addiction.

Because more than 90% of index head and neck squamous cell carcinoma diagnoses are stage I to IVb, initial treatment in the vast majority is curative in intent (see https://www.nccn.org/professionals/physician). The multidisciplinary team must optimally deploy and sequence three key modalities: surgery, radiation therapy, and systemic therapy.

Treatment Modalities

The primary curative modality for head and neck squamous cell carcinoma is either surgery or radiation therapy, whereas systemic therapy serves as an adjunct to radiation therapy.[11] The selection of a specific multimodality treatment plan is tailored to anatomic site, stage, organ preservation, and goals of care.[12,13]

Surgery

In head and neck surgery, the advent of minimally invasive endoscopic procedures incorporating transoral CO_2 laser microsurgery or robotic surgery has markedly limited the morbidity of surgical exposure to the oropharynx. Avoiding violation of the soft tissue framework of the head and neck, including muscles, ligaments, and bones, decreases hospital stay and enhances function and cosmesis compared to historical open procedures.[14]

Radiation Therapy

The dissemination of intensity-modulated radiation therapy techniques,[15] including image-guided radiation therapy, improves the precision and accuracy of delivery of radiation therapy to the tumor and regional nodes while sparing intricate and vulnerable head and neck structures. Intensity-modulated radiation therapy reduces the important long-term morbidity of xerostomia (dry mouth). Although hyperfractionated radiation therapy is superior to conventional fractionation and is an appropriate standard of care when concomitant chemotherapy is not indicated, the value of altered fractionation regimens is uncertain when concomitant chemotherapy is used.[A1]

Systemic Therapies

Systemic therapies used in head and neck cancer include cytotoxic chemotherapy, molecular targeted therapy, and immunotherapy under expert supervision. The core cytotoxic chemotherapies are cisplatin, 5-fluorouracil, and docetaxel. Cisplatin is used in both the primary setting, concurrent with radiation therapy, or as first-line treatment for recurrent/metastatic disease. 5-Fluorouracil and docetaxel are predominantly used in the recurrent/metastatic setting. Cetuximab, which is a murine-human chimeric IgG1 monoclonal antibody against EGFR, is used during definitive radiation therapy for patients who are not candidates for cisplatin and may be used in the recurrent/metastatic setting. Nivolumab and pembrolizumab, which are IgG4 monoclonal antibodies against PD-1, are indicated in the recurrent/metastatic setting and are under investigation for curative intent.

Oral Cavity Cancer

Cancers of the oral cavity are resistant to radiation and are preferably managed with primary surgery, which generally should include lymph node dissection at the time of the primary surgery.[16] The advancement of modern reconstruction techniques, including free tissue transfer with microvascular reconstruction, has enhanced functional and cosmetic outcomes. In the clinically negative (N0) neck, sentinel node biopsy provides equivalent survival and lower morbidity compared with modified radical neck dissection.[A2]

The recommendation for adjuvant radiation therapy is based on the presence of adverse pathologic features, including extension to extracapsular lymph nodes, positive surgical margins, a pT3-4 primary tumor, N2-3 nodal disease, and perineural or lymphovascular invasion. The addition of concurrent cisplatin chemotherapy to adjuvant radiation therapy under expert guidance improves locoregional control and survival in patients with pathologic high-risk head and neck squamous cell carcinoma, defined as the presence of extracapsular nodal extension or a positive surgical margin.

HPV-Unrelated Oropharyngeal Squamous Cell Carcinoma and Hypopharynx Cancer

The majority of patients with hypopharyngeal and p16-negative oropharyngeal squamous cell carcinoma present with locally advanced disease and are treated with an organ preservation approach (i.e., primary radiation therapy). In stage III or higher disease, concurrent systemic therapy with cisplatin or cetuximab under expert supervision increases locoregional control and survival compared with radiation therapy alone, with cisplatin generally being preferable to cetuximab. The decision to offer concurrent systemic therapy also depends upon physiologic fitness, because both acute and late toxicities are magnified in patients who are frail or have a low performance status. Although concurrent cisplatin improves locoregional control in people over age 70 years, it does not improve survival, probably because of competing comorbid conditions or late toxic effects such as aspiration pneumonia. Cetuximab has a more favorable systemic toxicity profile than cisplatin, with fewer renal, bone marrow, and otologic adverse events, so concurrent cetuximab-radiation therapy is an appropriate standard of care for locally advanced head and neck squamous cell carcinoma in patients who are unfit for cisplatin.[17]

HPV-Associated Oropharyngeal Squamous Cell Carcinoma

Patients with HPV-associated oropharyngeal squamous cell carcinoma have a markedly better prognosis than their HPV-negative counterparts, whether treated with primary surgery or radiation therapy. Treatment standards under expert supervision include definitive (chemo)radiation therapy or minimally invasive, transoral surgery followed by adjuvant (chemo)radiation therapy. When a definitive radiation approach is selected, cisplatin-radiation therapy is superior to cetuximab-radiation therapy and remains the standard of care.[A3,A4] Deintensification strategies under investigation include induction chemotherapy followed by lower-dose radiation therapy, minimally invasive surgery followed by lower-dose versus standard adjuvant radiation therapy,[A5] and lower-dose radiation therapy with either concurrent cisplatin or nivolumab.[A6]

Larynx Cancer

An important general principle for the treatment of larynx cancer is preservation of a functional larynx.[18] Maintaining the larynx without adequacy of its three key functions, airway patency, pharyngeal swallowing, and voice, is not an appropriate goal. For patients with early-stage T1-2 larynx cancer, single-modality treatment with either radiation therapy or larynx preservation surgery results in 90% long-term laryngectomy-free survival.

For patients with locally advanced larynx cancer, the combination of radiation therapy and chemotherapy under expert supervision is the preferred approach for organ preservation. The two evidence-based standards include cisplatin-based induction chemotherapy followed by definitive radiation therapy or concurrent cisplatin-radiation therapy.

Evidence also supports the feasibility of larynx preservation in appropriately selected patients with limited T4 disease. Patients who are likely to be more appropriate for up-front total laryngectomy include patients who have destructive tumors affecting both vocal cords, patients who are frail or have a poor performance status, and patients who are unlikely to adhere to a 7-week radiation therapy program that requires daily attendance.

Nasopharyngeal Carcinoma

Radiation therapy is the cornerstone of curative treatment for localized nasopharyngeal carcinoma. Radiation therapy alone is noninferior to chemoradiotherapy for low-risk localized disease,[A7] but induction chemotherapy with cisplatin and gemcitabine prior to concurrent cisplatin-radiation therapy significantly improves recurrence-free and overall survival compared with chemoradiotherapy alone in patients with locoregionally advanced disease.[A8] Neck dissection is recommended if locoregional treatment fails or disease recurs. For recurrent/metastatic disease, the addition of camrelizumab (an anti-PD-1 antibody) to gemcitabine plus cisplatin increases progression-free survival and is now a first-line standard.[19,A9]

Salivary Gland Malignancies

The primary curative-intent treatment for salivary gland malignancies is surgery, followed by reconstruction. Adjuvant radiation therapy is frequently offered for stage III-IVb disease. In recurrent or metastatic disease, platinum-based chemotherapy remains a palliative option, but its clinical activity is limited, and targeted molecular approaches are an increasingly utilized option under expert oversight. The TRK inhibitor larotrectinib can yield a response rate of 75% for tumors that harbor an *NTRK* gene fusion, including salivary gland cancers,[A10] and this agent compares favorably with cytotoxic chemotherapy. Combined androgen blockade can provide about a 40% overall response rate with excellent tolerability in patients who have advanced salivary duct carcinoma. HER2neu-enriched tumors may respond to ado-trastuzumab emtansine or other clinically available HER2 inhibitors.[20] The existence of multiple unique gene fusions within salivary gland cancers also raises the promise of immunotherapy against the peptide neoantigens translated from these fusion sites.

Recurrent/Metastatic Head and Neck Squamous Cell Carcinoma

For patients with locally advanced head and neck squamous cell carcinoma, the major cause of mortality is failure of locoregional control. In a minority of patients with isolated locoregional relapse, salvage surgery or re-irradiation can lead to durable long-term disease control but at the expense of substantial

morbidity.[21] For oligometastatic pulmonary disease, metastasectomy may occasionally be curative, particularly in patients who have HPV-associated cancer.

The majority of patients with locoregional recurrence and/or distant metastatic disease are candidates for palliative systemic therapy, depending upon performance status, comorbidities, and goals of care. The standard palliative systemic management of recurrent/metastatic head and neck squamous cell carcinoma is pembrolizumab (an anti-PD-1 monoclonal antibody), either as monotherapy or in combination with platinum and 5-fluorouracil[A11,A12] under expert supervision unless contraindicated by an autoimmune disorder. For the platinum-refractory disease, either nivolumab or pembrolizumab improves survival relative to single-agent chemotherapy or cetuximab.[A13] Treatment with PD-1 checkpoint blockade can provide long-term disease control in 10 to 20% of patients with recurrent/metastatic head and neck squamous cell carcinoma. HPV-specific immunotherapies under development include T cells engineered with a T-cell receptor targeting HPV-16 E7[22] and therapeutic HPV vaccines.[23]

Supportive and Palliative Care

Due to its anatomic location, head and neck squamous cell carcinoma and its treatment impact fundamental human functions, including voice, facial expression, eating, and breathing.[24] The care team must address both physical and psychological distress, often stemming from pain, nausea, malnutrition, fatigue, impaired communication, and social isolation. Even when cured from head and neck cancer, survivors experience a high burden of symptoms, including psychological distress and poor quality of life. Survivors have a high rate of suicide, almost twice that of survivors of cancers at other sites. In patients with recurrent/metastatic head and neck cancer, the burden of symptoms is particularly profound at the end of life, especially when locoregional disease is uncontrolled. The unique palliative challenges in this setting include the management of foul-smelling, ulcerative masses; decisions regarding the palliative role of enteral feeding tubes or tracheostomy; and preparation of the patient and caregivers for acute terminal events resulting from loss of airway or carotid exsanguination. Due to the unique burden of symptoms across the natural history of head and neck squamous cell carcinoma, early and continuous involvement of palliative care specialists is ideal.

PREVENTION

Environmental Head and Neck Squamous Cell Carcinoma

Patients with an index HPV-negative head and neck squamous cell carcinoma develop a second primary tumor of the upper aerodigestive tract at the alarming rate of 3 to 6% per year. The most important strategy for decreasing primary or secondary risk for head and neck squamous cell carcinoma is withdrawal of the offending carcinogen.[25] Although tobacco cessation reduces the incidence of second primary tumors, the risk is not reduced in the first 5 years and never returns to baseline. Although high-dose isotretinoin, a synthetic vitamin A analog, can reverse oral premalignant lesions and prevent second primary tumors following an index head and neck squamous cell carcinoma, isotretinoin is too toxic for chronic administration, and the risk returns to baseline upon its discontinuation. Ongoing investigations focus on whole plant-based interventions and on therapies aimed to reprogram the permissive immune microenvironment that tolerates oral epithelial transformation.

HPV-Associated Head and Neck Squamous Cell Carcinoma

HPV vaccination (Chapters 15 and 344) has an estimated 93% efficacy for preventing oral HPV[A14] and likely will prevent HPV-associated oropharyngeal cancer, although randomized clinical trials designed to demonstrate a reduction in HPV-associated oropharyngeal carcinoma are impractical because of the long latency period. HPV vaccination is recommended for all males and females ages 9 to 26 years and can be administered from ages 27 to 45 years after shared decision making.[26] The high risk of subsequent oropharyngeal cancers among persons who harbor oral HPV[27] raises the possibility of future minimally invasive screening protocols.

PROGNOSIS

Environmental Head and Neck Squamous Cell Carcinoma

The prognosis of HPV-negative head and neck squamous cell carcinoma is dependent upon stage and performance status. Although patients with stage I to II disease have an overall 5-year survival of 60 to 90%, the corresponding survival rate for patients who present with locally advanced stage III to IVb disease is only 30 to 50%. At the time of locoregional or distant metastatic relapse, median survival with modern palliative systemic therapy is 1 year.

HPV-Associated Head and Neck Squamous Cell Carcinoma

Patients with HPV-associated oropharyngeal squamous cell carcinoma have a more favorable prognosis than patients with HPV-negative cancer. Patients with stage I to II disease experience a 5-year overall survival of 72 to 89%. In nonsmokers with stage I to II disease, the 5-year overall survival rates approach 95%. Patients with stage III HPV-associated oropharyngeal squamous cell carcinoma have an intermediate prognosis, with a 5-year overall survival of 46 to 72%. When patients with HPV-associated oropharyngeal squamous cell carcinoma develop recurrent/metastatic disease, median survival is approximately 2 years, twice the survival rate for HPV-negative head and neck squamous cell carcinoma. This survival disparity in the recurrent/metastatic setting may be explained by better prognostic characteristics, including younger age and lower comorbidity scores, as well as the enhanced sensitivity of HPV-transformed cancers to chemotherapy.

Nasopharyngeal Cancer

Intensity-modulated radiation therapy can achieve locoregional control in >90% of stage I to II nasopharyngeal carcinomas. For locoregionally advanced disease, 5-year survival is about 85% with induction plus concurrent chemotherapy. Current median survival rates are about 29 months for metastatic disease.[28]

Salivary Gland Cancers

Prognosis is favorable in the setting of stage I to II disease, intermediate in the setting of stage III to IVb disease, and poor in the setting of stage IVc disease. For adenoid cystic carcinomas, the primary tumor is often well controlled following surgery and/or radiation, but the disease may relapse years later with involvement of cranial nerves and the base of the skull. Delayed lung metastases are also a common feature, so these patients are frequently followed for a decade or more by their treating oncologists.

177 LUNG CANCER AND OTHER PULMONARY NEOPLASMS

FADLO R. KHURI

Lung cancers grow from a single abnormal cell or small group of abnormal cells to develop into large macroscopic masses that may be several centimeters in diameter. Most lung cancers originate from the bronchial epithelium and are termed carcinomas. Primary noncarcinoma lung cancers are less common and include carcinoid, pulmonary blastomas (more common in younger patients), and sarcomas. Abnormal lung tissues range in histologic grade from mildly atypical cells to aggressive cancers. Lesions such as atypical adenomatous hyperplasia are considered preinvasive lesions, with a continuum of cellular atypia through adenocarcinoma.

BRONCHOGENIC LUNG CANCER

DEFINITION

Lung cancer, or bronchogenic carcinoma, is a proliferative malignant neoplasm arising from the primary respiratory epithelium. Lung cancer is generally divided into two major histologic groups: *non–small cell lung cancer* (NSCLC), which accounts for approximately 85% of all lung cancers, and *small cell lung cancer* (SCLC).

EPIDEMIOLOGY

Lung cancer is by far the leading cause of cancer-related mortality globally. An estimated 2.2 million new cases diagnosed worldwide each year account for nearly 11% of all cancers and cause an estimated 1.8 million annual deaths. Among men, lung cancer is the most common malignant neoplasm (worldwide incidence rate of 31.5 per 100,000), whereas in women, lung cancer incidence (14.6 per 100,000) trails breast, cervix, and colon cancers. The incidence and mortality related to lung cancer in men have declined during the last two decades in Western countries but continue to increase in the developing world.[1] In women, lung cancer deaths are increasing in most regions of the world. The most dramatic increases in lung cancer incidence and death globally are in China, which has experienced over a 4.5-fold increase in lung cancer–related deaths during the past 3 to 4 decades.

Risk Factors

Cigarette smoking is the most common risk factor for lung cancer, with roughly 85% of lung cancer patients having a tobacco-smoking history and approximately 50% being former smokers (defined as free from smoking for at least 12 months before diagnosis). The risk for developing lung cancer correlates with the number of cigarettes smoked per day and the cumulative duration of smoking time.[2] Patients with a smoking history of at least 20 to 30 pack-years (defined as one pack per day of cigarettes for 20 to 30 years) are at substantially increased risk for lung cancer.

Since the release of the first U.S. Surgeon General's Report on the Hazards of Smoking in 1964, the prevalence of cigarette smoking has declined considerably in the United States but continues to increase at an alarming rate in developing and third world countries. As a result, the number of cases of lung cancer diagnosed annually is likely to rise during the next few decades, and it is estimated that the majority of lung cancer cases will occur outside the United States and Europe by the year 2030. Smoking cessation is associated with a gradual reduction in risk of developing lung cancer, although it does not reach that of a never-smoker. Second-hand exposure to smoke is another risk factor that contributes to nearly 1% of all cases of lung cancer.

Because only about 11% of heavy smokers develop lung cancer, genetic susceptibility to lung cancer also appears to play a role. Patients with a family history of early lung cancer (before 60 years of age) have a two-fold higher risk for developing lung cancer. Women appear to be at a higher risk for lung cancer at the same smoking exposure level as that of men.

Occupational exposure to asbestos leads to an estimated four-fold higher risk of lung cancer, with cigarette smoking having an additive effect on risk. The latency between asbestos exposure and the development of lung cancer is several decades, and risk is related to the duration of exposure as well as to the quantity and the type of asbestos fiber. However, all forms of asbestos are carcinogenic.

Radon exposure has also been implicated in the development of 5 to 8% of lung cancer cases. Household exposure to radon, which results from the radioactive decay of uranium, is high in certain geographic regions. Exposure to ionizing radiation in the form of therapeutic radiation or frequent diagnostic radiographic tests is also associated with a higher risk for developing lung cancer. Similarly, exposures to metals (including arsenic, nickel, and chromium), silica, and general air pollution (including biomass fuels such as coal and wood smoke) are also associated with the risk of lung cancer but to a lesser degree compared with ionizing radiation. The human immunodeficiency virus is associated with a 3.6-fold increased risk of developing lung cancer.

PATHOBIOLOGY

Pathology

Lung cancer is broadly subdivided into NSCLC and SCLC on the basis of their distinct histopathology, biologic behavior, and response to therapies. NSCLC comprises *adenocarcinoma*, *squamous cell carcinoma*, and *large cell carcinoma* subtypes. In addition to morphologic features, immunohistochemical studies are important in establishing the histologic subtype of NSCLC.

Adenocarcinomas

Adenocarcinoma has increased in incidence over the past several decades and now represents over 50% of all lung cancers. Never-smokers who develop lung cancer most frequently have adenocarcinoma. Adenocarcinoma has a higher predilection for developing distant metastases compared with squamous cell lung cancers. Adenocarcinoma specimens usually stain positive for cytokeratin 7, thyroid transcription factor-1 (TTF-1), and Napsin-A, but they stain negative for cytokeratin 20.

Lung adenocarcinoma can be divided into preinvasive, minimally invasive, and invasive types. *Atypical adenomatous hyperplasia* refers to a localized proliferative lesion consisting of atypical type II pneumocytes or Clara cells and measuring less than 5 mm. *Adenocarcinoma in situ*, which refers to lesions that are smaller than 3 cm and that lack any invasive characteristics, was previously referred to as bronchioloalveolar carcinoma or noninvasive adenocarcinoma. Lesions 3 cm or smaller with a predominantly lepidic pattern and with invasion of less than 5 mm in greatest dimension are referred to as *minimally invasive adenocarcinoma*. Invasive adenocarcinoma represents nearly 90% of all cases of adenocarcinoma. Based on the predominant characteristic features, it is categorized as lepidic, acinar, papillary, micropapillary, or solid predominant with mucin production.

Squamous Cell Carcinoma

Squamous cell lung cancer is decreasing in incidence in the United States, most likely because of the changing smoking habits of the population. Squamous tumors of the lung are generally centrally located and are almost always seen in patients with a significant smoking history. Squamous dysplasia and squamous cell carcinoma in situ are preinvasive lesions that can develop into invasive cancers.

The majority of squamous cell tumors stain positive for p40 and p63, which are members of the p53 family of proteins, whereas adenocarcinomas occasionally stain positive for p63. On the basis of these findings, a panel of markers including TTF-1, p63, and p40 is frequently evaluated in diagnostic specimens of patients with lung cancer to identify the histologic subtype accurately (E-Table 177-1).

Large Cell Carcinoma

Large cell carcinoma represents 3 to 4% of NSCLC and is characterized by a high mitotic rate, necrosis, and morphologic features of NSCLC. Large cell tumors stain positively for neuroendocrine markers such as chromogranin A and synaptophysin. Large cell carcinoma is often difficult to diagnose accurately owing to an abundance of necrotic tissue and a poor degree of differentiation, so diagnosis requires an adequate tissue specimen. Large cell carcinoma is strongly associated with a history of prior smoking.

Small Cell Lung Cancer

SCLC is diagnosed in approximately 13% of lung cancer cases in the United States, and its incidence has gradually declined during the past several decades. SCLC is strongly associated with smoking and is rare in never-smokers. Pathologic diagnosis can be challenging because of an abundance of necrotic tissue but is established by characteristic features, such as a high degree of

ABSTRACT

Lung cancer is a common malignancy and the leading cause of cancer-related mortality globally, resulting in an estimated 1.8 million deaths each year worldwide. It is characterized by presentation at an advanced stage, aggressive disease course, and modest sensitivity to systemic therapies. Lung cancer is broadly subdivided into two major histologic types: non–small cell lung cancer (NSCLC) and small cell lung cancer (SCLC). NCSLC accounts for approximately 85% of all lung cancer cases and comprises adenocarcinoma, squamous cell carcinoma, and large cell carcinoma subtypes. Cigarette smoking is the most common risk factor for lung cancer, accounting for about 85% of all cases, although the number of never-smokers with lung cancer has increased in recent years. Specific molecular abnormalities in lung cancer include mutations in the epidermal growth factor receptor (EGFR) gene and rearrangements of the anaplastic lymphoma kinase (ALK) gene. Many of these molecular changes represent therapeutic targets and have led to the development of specific targeted therapies. Agents targeting the PD-1 pathway have led to a paradigm shift in the treatment of lung cancer. Increased understanding of disease biology, earlier detection, improved treatment agents and modalities, tumor sequencing, and improved supportive care measures are all rapidly changing the clinical landscape of lung cancer. The mortality related to lung cancer has decreased by 2 to 3% annually in the United States over the past few years.

mitosis and necrosis. The diagnostic evaluation of SCLC includes immunostaining for TTF-1, chromogranin, synaptophysin, and CD56. Approximately 15% of SCLC specimens have mixed morphology with components of NSCLC.

Molecular Pathology

Whole-genomic sequencing has revealed that the mutational burden in specimens of adenocarcinomas from the lungs of persons who have never smoked is a log order of magnitude lower than the mutational burden in the lungs of persons who have ever smoked. Characteristic cytosine-adenine (C→A) nucleotide transversions are associated with tobacco exposure and are seen predominantly in lung adenocarcinomas from smokers rather than from those who have never smoked. The cause of the increasing number of lung cancers among never-smokers is unclear, but affected individuals are more likely to harbor certain genetic alterations in the tumor, such as mutations in the gene encoding epidermal growth factor receptor (EGFR) and rearrangement in the gene encoding anaplastic lymphoma kinase (ALK).[3]

Oncogenes

In lung adenocarcinoma, nearly two thirds of patients harbor an oncogenic mutation that can potentially be targeted with specific agents (E-Fig. 177-1A).[4] The most common are mutations involving *KRAS*, *EGFR*, *BRAF*, *HER2*, *MET*, and *PIK3CA* and gene rearrangements involving *ALK*, *RET*, and *ROS1*. *KRAS* mutations are present in approximately 25% of lung adenocarcinomas and are usually associated with cigarette smoking. The most common sites of mutation in *KRAS* include codons 12, 13, and 61, where the resulting amino acid substitutions cause impaired GTPase activity and constitutive activation of RAS signaling.

Mutations in *EGFR* are observed in nearly 15% of White and almost 40% of Asian patients with lung adenocarcinomas. Deletion mutations in exon 19 and a point mutation in exon 21 are located in the tyrosine kinase–binding domain of the receptor and result in constitutive activation of the signaling pathway, thereby leading to proliferation, evasion of apoptosis, and enhanced angiogenesis. Patients with *EGFR*-activating mutations can derive robust and durable clinical benefit from treatment with EGFR tyrosine kinase inhibitors; however, most of the benefit is limited in duration and within 12 to 24 months, and nearly 60% of patients treated with first- or second-generation inhibitors will develop a secondary mutation in exon 20(T790M) that confers resistance to this therapy. In some patients with lung adenocarcinomas, this exon 20(T790M) mutation can also be found de novo along with an exon 19 or 21 mutation before exposure to EGFR tyrosine kinase inhibitor therapy. Another common mechanism of acquired resistance to EGFR tyrosine kinase inhibitor therapy is amplification of the growth factor receptor c-Met.

In approximately 5% of patients with lung adenocarcinomas, gene rearrangement involving *ALK* is observed. Clinical features associated with the *ALK* gene rearrangement include never-smokers, signet ring features on histopathologic evaluation, and younger age. The fusion gene results from inversion or translocation of portions of the *echinoderm microtubule-associated protein-like 4 (EML4)* with the *ALK* gene and leads to activation of downstream signals that can be inhibited by specific ALK kinase inhibitors such as crizotinib. The *ALK* gene rearrangement can be detected by fluorescence in situ hybridization or by immunohistochemistry. Other fusion abnormalities involving the *RET* and *ROS1* genes are each observed in 1% of lung adenocarcinoma specimens. It is noteworthy that *EGFR* and *KRAS* mutations and *ALK* gene rearrangements are usually mutually exclusive.

Squamous cell carcinoma has an entirely different spectrum of molecular abnormalities (E-Fig. 177-1B), including common mutations in *p53*, *PTEN*, *PIK3CA*, *KEAP1*, *DDR2*, and *RB1*. Amplification of the gene for *fibroblast growth factor receptor* (FGFR) is also noted in 10 to 20% of squamous cell lung cancers.

Tumor Suppressor Genes

The function of multiple tumor suppressor genes (e.g., *p53*, *Rb*, *LKB1*, and a number of genes found on the short arm of chromosome 3 [*3p*]) is frequently lost in lung cancer. Mutation or loss of *p53* correlates with cigarette smoking and is detected in some preneoplastic lesions of the lung. Mutations of *p53* are common in both NSCLC (≈50%) and SCLC (≈80%). Mutations in *LKB1* are also common in NSCLC. The *STK11/LKB1* gene, which encodes a *serine/threonine kinase*, regulates cell polarity and functions as a tumor suppressor. One of the earliest genetic abnormalities in lung cancer occurs during the deletion of genetic material on chromosome 3p (p14 to p23). The deletion occurs in approximately 50% of NSCLC and 90% of SCLC patients. The *FHIT* (fragile histidine triad) gene (3p14.2), which is abnormal in many lung cancers, may function as a tumor suppressor gene by limiting tumor growth and enhancing apoptosis. The Rb protein is not expressed in 90% of SCLC because of mutation or deletion. In NSCLC, Rb is normally expressed, but when Rb is phosphorylated, uncontrolled cell division can occur.

Epigenetics

Epigenetic modifications involving changes in DNA methylation are common in lung cancer and include hypomethylation, dysregulation of DNA methyltransferase I, and hypermethylation. Genes that are methylated in NSCLC include *p16*, *RARB*, *RASSFIA*, *MGMT* (methylguanine-methyltransferase), and death-associated protein kinase (DAP-kinase). Hypermethylation in lung cancer can often silence tumor suppressor genes, thereby promoting dysregulated cell growth. Silencing of tumor suppressor genes in histologically normal lymph nodes in patients with resectable NSCLC is associated with higher likelihood of disease relapse.

CLINICAL MANIFESTATIONS

Currently, only 15% of patients with lung cancer are asymptomatic when they are initially diagnosed. These early lung cancers often are manifested as a pulmonary nodule (defined as a rounded opacity, well or poorly defined, measuring up to 3 cm in diameter), first seen incidentally on a chest radiograph obtained for other reasons (e.g., a preoperative study) or on a screening computed tomographic (CT) scan.

Most patients have symptoms and signs that are caused by the pulmonary lesion itself: local tumor growth, invasion, obstruction, intrathoracic-regional tumor spread to lymph nodes and adjacent structures, distant extrathoracic spread of disease, or a paraneoplastic syndrome. Common presenting symptoms of lung cancer include cough, dyspnea, pain, hemoptysis, and weight loss. Anorexia occurs in about 30% of patients, fatigue in one third of patients, and anemia and fever in 10 to 20% of patients. More than 80% of patients initially have three or more symptoms or signs as a result of the lung cancer. Because the majority of patients with lung cancer have other tobacco-related cardiopulmonary diseases, such as chronic obstructive pulmonary disease (Chapter 76) and ischemic heart disease (Chapters 56 to 58), these overlapping symptoms often result in a delay in diagnosis of the underlying malignant disease. Symptoms that can result from local invasion or metastasis of the tumor include headache, bone pain, airway obstruction, cough, and hemoptysis. Paraneoplastic syndromes (Chapter 164) associated with lung cancer include the syndrome of inappropriate antidiuretic hormone (Chapter 102), hypercalcemia (Chapter 227), pulmonary hypertrophic osteoarthropathy (Chapter 254 and Fig. 254-1), Eaton-Lambert myasthenic syndrome (Chapter 390), and Cushing syndrome (Chapters 164 and 208). Hypercalcemia is common in squamous cell histology, whereas the syndrome of inappropriate antidiuretic hormone, Eaton-Lambert myasthenic syndrome, and Cushing syndrome are most commonly associated with SCLC.

DIAGNOSIS

Solitary Pulmonary Nodule

Asymptomatic solitary pulmonary nodules less than 3 cm in diameter with normal surrounding lung architecture are found incidentally in up to 0.2% of chest radiographs.[5] A solitary pulmonary nodule can be the first sign of early lung cancer, but about 95% of such lesions are noncancerous and most often are granulomas or intrapulmonary lymph nodes. Smaller nodules are likely to be benign. The potential for these lesions to be malignant increases with the patient's age, the size of the nodule, the nodule's rate of growth, a history of smoking, and any changes compared with prior imaging studies.

The evaluation (Fig. 177-1) begins with computed tomographic (CT) scanning. Nodules are categorized as small solid (<8 mm), large solid (≥8 mm), or subsolid. Subsolid nodules are divided into ground-glass nodules (no solid component) and part-solid nodules (both ground-glass and solid components). The likelihood of malignancy is <1% for nodules that are less than 6 mm and 1 to 2% for solid nodules that are 6 mm to 8 mm. These low-risk nodules can be monitored with serial CT scans. A pulmonary nodule that has not changed in size for more than 2 years is probably benign.

For larger nodules, which have a higher likelihood of malignancy, CT characteristics suggestive of malignancy include irregular margins, spiculation, invasion of adjacent structures, lymphadenopathy, and distant metastases.[6] Further imaging is warranted (e.g., positron emission tomography [PET]), and suspicious nodules should undergo definitive biopsy. For nodules that are partly solid, diagnostic strategies are typically guided by the size of the solid component.

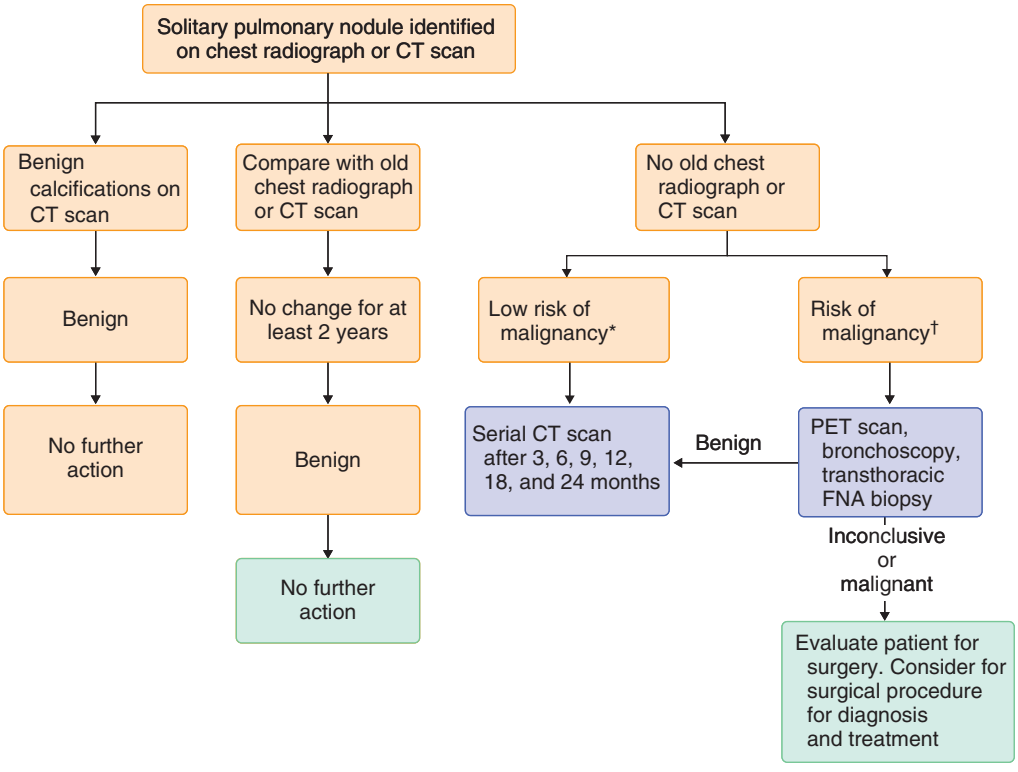

FIGURE 177-1. Evaluation of a patient with a solitary pulmonary nodule. *Patient with a minimal or absent history of smoking and other known risk factors for the development of lung cancer and a nodule 8 mm or smaller. †Patient with a history of smoking and other risk factors for the development of lung cancer and a nodule 8 mm or larger. CT = computed tomography; FNA = fine-needle aspiration; PET = positron emission tomography.

Noncancerous causes of a solitary pulmonary nodule include granulomatous diseases (e.g., sarcoidosis [Chapter 83] and histoplasmosis [Chapter 308], coccidiomycosis [Chapter 308], rheumatoid arthritis [Chapter 243]) and benign hematomas, as well as scars from prior pulmonary infections.

In screening studies, new solid nodules are detected at each round of screening in 5 to 7% of individuals. New nodules have a high probability of malignancy even when small, thereby suggesting more aggressive follow-up of new nodules that appear upon serial screening CT than for nodules that are detected at baseline imaging.

Initial Evaluation

With the advent of CT screening, a greater percentage of patients with lung cancer are being diagnosed before the onset of symptoms. In patients with clinical or radiographic findings suggestive of lung cancer, CT scans of the chest and abdomen are indicated to determine the location of the primary tumor, involvement of mediastinal lymph nodes (Fig. 177-2), and spread to other anatomic sites.

Invasive Diagnostic Procedures

Establishing the Diagnosis

Accurate diagnostic characterization of lung cancers is essential because the presence or absence of mediastinal nodal metastases is crucial in determining prognosis, assessing resectability, and selecting the appropriate treatment strategy for primary lung cancer.[7] For patients with localized lung tumors that are suggestive of cancer, it is reasonable to proceed with surgical resection without a diagnostic biopsy if all other potential causes are excluded. Commonly, however, a biopsy is necessary to establish the diagnosis of lung cancer and to define its histology before proceeding with surgery. The most accessible site with the least invasive method is the preferred approach to obtaining diagnostic tissue. Although a fine-needle aspiration procedure is often adequate to establish diagnosis and can be accomplished by a transthoracic approach or by bronchoscopy, the yield is often inadequate to conduct molecular studies. Therefore, a core needle biopsy to obtain sufficient tissue is recommended for patients with suspected lung cancer.[8]

For patients who present with pleural or pericardial effusions, transthoracic aspiration of fluid is typically sufficient for diagnosis and staging. Cell blocks prepared from the fluid can be used to conduct molecular studies, although the success rate depends on the number of viable cancer cells in the specimen. The diagnostic yield of pleural fluid in patients with malignant effusion is approximately 50 to 70%. In instances in which repeated aspiration of pleural fluid is nondiagnostic, a video-assisted thoracoscopy procedure might be necessary to establish diagnosis.

Staging Thoracic Disease

Enlarged lymph nodes identified by CT or positron emission tomography (PET) require histologic confirmation. Whether all patients require invasive mediastinal staging before surgical resection or other local treatment is uncertain because only 5 to 15% of patients who have peripheral T1 tumors and a negative mediastinum by CT or PET scanning have mediastinal nodal metastases.

Transbronchial needle aspiration allows staging of the mediastinum during diagnostic bronchoscopy. The sensitivity of transbronchial needle aspiration is dependent on the size and location of the lymph nodes (see Fig. 177-2) as well as on the size of the needle and is best suited for large, clinically positive lymph nodes. Endobronchial ultrasound can guide transbronchial fine-needle aspiration and provide an overall sensitivity approaching 90%. When combined with esophageal ultrasound-guided fine-needle aspiration (which provides access to lymph node stations 7, 8, and 9), the sensitivity can exceed 90%. Other diseases that are also associated with enlarged and metabolically active mediastinal lymph nodes include sarcoidosis, tuberculosis, and multiple infectious causes, generally of a fungal (e.g., histoplasmosis, coccidioidomycosis), atypical bacterial, or viral nature, so nodal tissue must be obtained.

Mediastinoscopy involves surgical assessment of mediastinal lymph nodes to determine tumor involvement. Cervical mediastinoscopy (which provides access to lymph nodes at stations 2, 4, 7, and often 10) has a complication rate of 2% but with few life-threatening complications. With video mediastinoscopy, sensitivity and specificity exceed 97%. Anterior mediastinotomy provides access to lymph node stations 5 and 6 (aortic and aortopulmonary window), which are generally not accessible with cervical mediastinoscopy.

Diagnostic Imaging

In conjunction with standard thoracic imaging procedures, additional sites of disease may require evaluation based on presenting complaints. The most common sites of lung cancer metastases include the contralateral lung, liver, adrenal gland, bones, and brain. Imaging of the brain is recommended to evaluate for metastasis in patients with suggestive symptoms and signs as well as in

Included is the proposed grouping of lymph node stations into "zones" for the purposes of prognostic analyses. (From Rusch VW, Asamura H, Watanabe H. The IASCL lung cancer staging project. A proposal for a new international lymph node map in the forthcoming seventh edition of the TNM classification for lung cancer. *J Thorac Oncol*. 2009;4:568-577.)

patients who have a lung adenocarcinoma larger than 3 cm and evidence of mediastinal nodal involvement. Magnetic resonance imaging (MRI) and CT scan with contrast enhancement are both acceptable modalities to evaluate for brain metastases, but MRI is preferred for its superior sensitivity. Radionuclide study of the bones is indicated in patients with bone pain or an unexplained elevation in serum alkaline phosphatase level.

PET scanning is part of staging in patients with localized lung cancer. MRI scan of the chest may be useful in determination of invasion of surrounding structures, such as the brachial plexus, in patients with tumors involving the superior sulcus of the lung, but its use in staging is generally restricted to preoperative settings.

Staging

Staging (Table 177-1) based on the size of the tumor, the presence of involved lymph nodes, and the presence of metastases guides therapeutic choices and is the most important determinant of prognosis in patients with lung cancer. The tumor size is categorized as less than 2, 2 to 3, 3 to 4, 4 to 5, 5 to 6, and then 7 cm. Currently, satellite nodules in the same lobe as the primary tumor

are categorized as T3, and nodules in another lobe of the ipsilateral lung are characterized as T4. Malignant pleural or pericardial effusion constitutes M1 disease. Presence of metastases within the thorax constitutes M1a, and extrathoracic disease is classified as M1b because patients with M1a disease have a slightly better prognosis than those with M1b.

Molecular Testing

A full gene expression profile can improve the diagnostic accuracy of the biopsy for detecting lung cancer and is often helpful for therapeutic decisions. Guidelines recommend routine molecular testing for *EGFR* mutation and *ALK* translocation in all newly diagnosed patients with advanced-stage lung adenocarcinoma. For patients with tumors of squamous cell histology, routine molecular testing is not yet recommended, but randomized clinical trials using this approach are in progress.

TREATMENT

Non–Small Cell Lung Cancer

Treatment for non–small cell lung cancer includes surgery, radiation, and medications, depending on the stage of the tumor and the fitness of the patient.[9,10]

Surgery

Surgical management plays the major role in the treatment of patients with stage I, stage II, and selected stage III NSCLC. However, nearly 40% of patients with early-stage lung cancer are not candidates for surgery because of limiting comorbid conditions. The commonly used parameters for inoperability include pulmonary functions with baseline forced expiratory volume in the first second of expiration (FEV_1) of less than 40%, predicted postoperative FEV_1 of less than 30%, and severely limited diffusion capacity. Such patients are referred to as medically inoperable despite the presence of localized disease and may be candidates for stereotactic body radiation therapy.

Lobectomy is the standard surgical procedure for patients who have localized lung cancer and who are medically fit. If anatomic resection cannot be achieved with lobectomy, bilobectomy or pneumonectomy might be necessary. Sleeve resection refers to removal of the tumor along with the bronchus and anastomosis of the remaining ends of the bronchial tree. Surgical resection can be achieved by performing an open thoracotomy or by video-assisted thoracoscopic surgery (VATS; Chapter 87), which is associated with lower morbidity, faster recovery from surgery, and better ability to administer postoperative systemic therapy.[A1] The ability to achieve an R0 resection (defined as no gross or microscopic tumor at the resection margins) is critical, and surgery should not be attempted if this outcome is not deemed feasible based on the preoperative evaluation. For patients with positive surgical margins, re-resection should be attempted whenever it is feasible. If not, postoperative radiation therapy should be administered. Robotic resection of lung cancers, including robotic lobectomy and pneumonectomy, has increased in use but is not as widely used as are VATS approaches.

Sublobar resections are not recommended because of the higher risk of local recurrence. An exception to this rule is for patients with peripheral tumors smaller than 2 cm, for which studies have demonstrated excellent outcomes.[A2]

Tumors involving the superior sulcus are managed with preoperative chemoradiotherapy to enhance tumor resectability and to gain local and distant tumor control. The decision to perform surgery for these anatomically challenging tumors depends on the extent of local invasion, involvement of the brachial plexus, and mediastinal lymph node involvement.

For stage III NSCLC with mediastinal nodal involvement, surgery alone is associated with a poor outcome, and chemoradiotherapy followed by surgery does not improve survival compared with chemoradiotherapy alone. For patients with multistation N2 disease or bulky nodal disease, surgical resection is not recommended. Clearance of mediastinal nodes after induction therapy might be the most important predictor of benefit from surgical resection, which calls for restaging of the mediastinum after induction therapy if surgery is contemplated.

Surgery can be considered under certain situations in patients with oligometastatic disease.[11] Surgical resection of both the primary and a solitary brain metastasis can result in 5-year survival rates of approximately 20%. Limited data also suggest resection of oligometastatic disease to the adrenal glands, but similar approaches with solitary metastasis at other distant sites are not recommended. This approach cannot be recommended for patients with mediastinal nodal involvement. Spinal cord compression (Chapter 164) is often a surgical emergency.

Radiation Therapy

Radiation therapy is an important part of multimodality therapy for NSCLC. It plays a major role in curative therapy for stage I to III disease and palliation of stage IV disease.

Stage I and Stage II NSCLC

Stereotactic body radiation therapy, which involves the delivery of high-dose radiation to a limited tumor volume after stereotactic localization, is an effective treatment option for patients who have T1 and node-negative T2 tumors but who are medically inoperable because of comorbid illness.[A3] In such patients, radiation therapy over three to five fractions can provide local control in almost 90% of cases. Stereotactic body radiation therapy also has considerable efficacy for peripheral tumors. Radiation therapy is also indicated for patients with positive surgical margins after surgery for early-stage NSCLC but not for patients with negative surgical margins or with involved mediastinal nodes.

Stage III NSCLC

Whereas surgery is appropriate for patients with T3N1 disease, radiation therapy results in improved outcomes for patients who have involvement of mediastinal lymph nodes.[12] A subset of N2-positive patients might benefit from multimodality therapy involving neoadjuvant chemoradiation followed by surgical resection, including stage IIIA patients with single-station or microscopic lymph node involvement and disease amenable to resection with lobectomy or bilobectomy. Preoperative radiation generally consists of 45 Gy once daily, but a dose of 60 Gy also is associated with acceptable safety results.

For patients with unresectable stage III disease, thoracic radiation therapy to a dose of 60 to 66 Gy in once-daily fractions with concurrent (rather than sequential) chemotherapy is the recommended treatment and is associated with a 5-year survival rate of 20 to 25%. The main adverse events include esophagitis and pneumonitis (depending on the extent of normal lung tissue and the dose of radiation received by normal lung tissue) that can occur immediately after radiation therapy or 6 to 9 months later.

Hyperfractionated radiation administered as two or three fractions per day is preferable to once-daily fractionation, particularly in squamous cell carcinoma, but logistical constraints have limited the adoption of this approach. In stage III patients, prophylactic cranial radiation can significantly decrease the risk of developing symptomatic brain metastases but does not improve survival.[A4]

Stage IV NSCLC

In patients with advanced-stage NSCLC, radiation therapy can be effective for palliation of spinal cord compression, brain metastasis, airway obstruction, hemoptysis, and pain. Spinal cord compression is usually managed with 30 Gy of external beam radiation therapy plus high-dose corticosteroids, but surgical decompression should precede radiation therapy when neurologic compromise is early and the patient has well-controlled systemic disease (Chapter 164).

For multiple brain metastases or oligometastatic disease not amenable to surgical resection, whole-brain radiation therapy (30 to 37.5 Gy given in 10 to 15 fractions) can be administered. Stereotactic radiosurgery can be used instead of whole-brain radiation therapy when low-volume brain metastases are limited to one to three lesions and when-brain lesions progress after whole-brain radiation therapy.

A short course of radiation therapy can provide pain control at sites of bone metastases or chest wall involvement. Palliative radiation therapy is also administered at 30 to 45 Gy during 2 to 3 weeks before the initiation of systemic therapy in patients who have systemic disease and who present with hemoptysis or postobstructive pneumonia.

Systemic Therapy

Systemic therapy refers to the use of cytotoxic agents, molecularly targeted therapy, or immunotherapy. Although it was initially developed for patients with advanced-stage lung cancer, the high propensity for metastasis of lung cancer

TABLE 177-2 TARGETED AGENTS IN LUNG CANCER THERAPY

MOLECULAR TARGET	FDA-APPROVED AGENTS
EGFR	Erlotinib Gefitinib Afatinib Osimertinib Necitumumab Dacomitinib
ALK translocation	Crizotinib Ceritinib Alectinib Brigatinib Lorlatinib
ROS1 rearrangement	Crizotinib Entrectinib
VEGF	Bevacizumab Ramucirumab
B-Raf V600E	Dabrafenib/trametinib
NTRK gene fusion	Larotrectinib Entrectinib
MET exon 14 skip mutation	Capmatinib
RET gene fusion	Selpercatinib Pralsetinib

ALK = anaplastic lymphoma kinase; EGFR = epidermal growth factor receptor; MET = metastatic; NTRK = neurotrophic tyrosine kinase; RET = rearranged during transfection; ROS1 = c-ros oncogene 1; VEGF = vascular endothelial growth factor.

TABLE 177-3 CHEMOTHERAPY REGIMENS IN ADVANCED NON–SMALL CELL LUNG CANCER

FIRST-LINE THERAPY	SECOND-LINE THERAPY
Cisplatin/docetaxel Cisplatin/gemcitabine Cisplatin/pemetrexed (non-squamous tumors) Cisplatin/vinorlebine Cisplatin/paclitaxel Carboplatin/paclitaxel +/−bevacizumab Carboplatin/docetaxel Carboplatin/pemetrexed (non-squamous tumors) Carboplatin/vinorelbine Carboplatin/gemcitabine	Docetaxel +/− ramucirumab Pemetrexed (non-squamous tumors) Gemcitabine Vinorelbine

cells has extended the use of systemic therapy to patients with earlier stages of the disease. A number of effective and well-tolerated cytotoxic agents are now used for the routine care of patients with lung cancer. In addition, many targeted agents (Table 177-2) have replaced standard chemotherapy as first-line agents for patients with specific mutations, and others are under clinical investigation.

Systemic Therapy in Early-Stage NSCLC

Even in the setting of optimal surgery, patients with early-stage NSCLC remain at high risk for disease recurrence or metastases due to the presence of micrometastasis, which can increasingly be quantified by the evaluation of circulating tumor cells or circulating tumor DNA. In stage IA disease, the potential benefits of chemotherapy are largely outweighed by the risks, and the overall effect is detrimental. For stage IB disease, adjuvant therapy may improve survival in patients whose tumors are larger than 4 cm, but this observation has yet to be validated in prospective trials. Drug options include cisplatin/vinorelbine or newer and better tolerated agents such as taxanes, gemcitabine, and pemetrexed under expert supervision. For stage II and stage IIIA NSCLC, four cycles of adjuvant cisplatin-based two-drug combination regimens under expert supervision provide a 5 to 15% absolute improvement in 5-year survival rates and are the standard of care.

Consistent with the success of molecularly targeted therapies in advanced-stage NSCLC, osimertinib can prolong disease-free survival in patients whose EGFR-mutated tumors have been treated with surgery and adjuvant chemotherapy.[A5] Efforts are underway to evaluate ALK inhibitors and immune checkpoint inhibitors in the adjuvant and neoadjuvant settings.

Locally Advanced NSCLC

For patients whose stage III disease is not amenable to surgical resection, concomitant administration of cisplatin or carboplatin-based chemotherapy plus radiation therapy under expert supervision is superior to sequential therapy. With modern combined chemoradiotherapy regimens, cure rates of nearly 20 to 25% are achieved in locally advanced NSCLC, with esophagitis and pneumonitis being the main toxicities. The addition of 12 months of consolidation therapy with durvalumab (a PD-L1 inhibitor) can improve survival to 43% at 5 years[A6] in patients with nonprogressive disease following chemoradiotherapy, and this approach is now the standard of care.

Advanced-Stage NSCLC

In patients with advanced-stage NSCLC, platinum-based systemic therapy under expert supervision improves overall survival and quality of life compared with supportive care alone. Carboplatin is a better tolerated outpatient option, and its dose-limiting toxicity is thrombocytopenia. Cisplatin treatment may be slightly more efficacious but is associated with nausea, emesis, nephrotoxicity, and neurotoxicity, although the availability of highly effective antiemetic agents has greatly improved its tolerability. Two-drug combination regimens are superior to monotherapy, with survivals in the 10- to 11-month range, and are recommended. Options to add to platinum-based therapy under expert supervision include etoposide, vinblastine, vindesine, vinorelbine, taxanes, gemcitabine, irinotecan, and pemetrexed (Table 177-3), with the choices among them based on consideration of toxicity, the preference of the patient, schedule, and cost. Combinations of three cytotoxic agents are not recommended because of their higher toxicity without a meaningful incremental benefit.

Targeted Systemic Therapies

Although targeted agents have shown great efficacy against lung cancer, they are unfortunately not curative. Resistance is universal to these agents, and therapy is usually continued until the disease progresses or unacceptable toxicity develops.

In patients with an activating *EGFR* mutation, treatment with gefitinib or erlotinib is associated with improvements in progression-free survival and quality of life compared with platinum-based chemotherapy, and adding gefitinib to platinum-based therapy prolongs survival compared with gefitinib alone.[A7] Afatinib, which is an irreversible EGFR tyrosine kinase inhibitor, is superior to chemotherapy[A8] in patients who have an activating *EGFR* mutation. Dacomitinib and osimertinib, which are second- and third-generation agents, respectively, appear to be more efficacious than earlier agents.[A9,A10] Osimertinib is also associated with favorable effects against brain metastases, which are a common clinical problem in patients with EGFR-mutated NSCLC.

The VEGF antibody bevacizumab is useful for advanced NSCLC with non-squamous histology, in which it significantly improves overall survival and progression-free survival when added to carboplatin and paclitaxel chemotherapy. Notable adverse events include bleeding, hypertension, proteinuria, and neutropenia.

In *ALK*-positive advanced-stage NSCLC, second-generation ALK inhibitors (ceritinib,[A11] alectinib,[A12] brigatinib,[A13] and lorlatinib[A14]) are now preferred over crizotinib as first-line therapeutic options. Lorlatinib is also used for patients who develop acquired resistance to prior ALK inhibitors.

BRAF-V600E mutations are observed in 1 to 2% of NSCLC. The combination of dabrafenib plus trametinib can result in response rates of 60% or more.[13] *RET* fusions are also oncogenic drivers in 1 to 2% of patients with NSCLC, and a durable response with acceptable toxicity is seen with selpercatinib[14] in untreated and platinum-treated patients with *RET* fusion-positive NSCLC.

KRAS G12C mutations account for approximately 40% of all KRAS mutations in NSCLC. Sotorasib and adagrasib, which are inhibitors of the KRAS G12C mutation, can provide a 35% response rate and median progression-free survival of about 7 months in advanced-stage NSCLC.[15,16] In patients whose tumors express human epidermal growth factor receptor 2 (HER2), transtuzumab deruxtecan can provide durable benefit.[17]

Immunotherapy

Inhibition of the programmed death (PD-1) ligand pathway with monoclonal antibodies reverses T-cell exhaustion and results in activation of host antitumor immune responses. Nivolumab, pembrolizumab, and cemiplimab are monoclonal antibodies against the PD-1 receptor, whereas atezolizumab and durvalumab are monoclonal antibodies against its ligand (PD-L1). Pembrolizumab can provide superior overall survival when added to or used instead of platinum-based chemotherapy for first-line therapy.[A15] For patients with PD-L1 expression level >50%, pembrolizumab monotherapy is associated with a 5-year survival rate of 32%. Atezolizumab[A16] and cemiplimab[A17] are also effective as monotherapy for first-line treatment for patients with PD-L1 expression ≥50%. Toripalimab and atezolizumab are also incrementally beneficial in combination with standard chemotherapy.[A18,A19] Nivolumab is effective as neoadjuvant therapy for resectable NSCL[A20] and also improves survival when combined with ipilimumab as a first-line therapy, with improvement in overall survival compared with chemotherapy.[A21] Another approach involving two cycles of platinum-based chemotherapy in combination with nivolumab and ipilimumab has also shown superiority over chemotherapy alone regardless of PD-L1 expression level or histology. Sugemalimab has also shown benefit with or after chemotherapy as first-line[A22] or secondary[A23] treatment of NSCLC.

Based on these results, these agents are now front-line therapy of advanced NSCLC, thereby representing a major shift in the treatment paradigm for

advanced NSCLC. Specifically, for patients with PD-L1 >50%, which represents approximately 25 to 30% of NSCLC, immune checkpoint inhibitor monotherapy is the present standard of care; for PD-L1 <50% or negative disease, either the combination of chemotherapy with immunotherapy or the combination of ipilimumab and nivolumab is considered an acceptable first-line therapy option. In these patients, immunotherapy is used for a maximum duration of 2 years in patients who demonstrate clinical benefit. The main toxicity associated with these agents is autoimmune events, with pulmonary toxicity being the most serious; fortunately, the majority of these events are treatable with appropriate supportive and immunosuppressive therapy.

Role of Histology in Choice of Chemotherapy

Preferred chemotherapy regimens can vary for different histologic subtypes of NSCLC. For example, cisplatin-pemetrexed is preferred for nonsquamous advanced-stage NSCLC, whereas cisplatin-gemcitabine is preferred for squamous cell tumors. Nanoparticle albumin-bound paclitaxel (nab-paclitaxel) is associated with a favorable response rate in patients with advanced squamous NSCLC. Furthermore, the monoclonal antibody necitumumab added to gemcitabine and cisplatin is better than gemcitabine and cisplatin alone for patients with advanced squamous NSCLC.[A24]

Maintenance Therapy

Immunotherapy is now the major maintenance therapy, with the optional application of chemotherapy. Pemetrexed is the only cytotoxic agent that has specifically shown benefit as maintenance therapy. Single-agent maintenance therapy also is useful in patients who have a demonstrated clinical benefit from four cycles of platinum-based combination chemotherapy. Current therapeutic strategies employ either a "switch maintenance" approach, which uses an alternative cytotoxic or targeted agent that has not been previously administered, or "continuation maintenance," which involves continuing only the nonplatinum agent beyond four cycles.

Salvage Therapy

Virtually all patients with advanced NSCLC will eventually experience progressive disease regardless of the extent of benefit from first-line chemotherapy. Salvage therapy for these patients under expert supervision provides a modest but real improvement in survival. For patients who did not receive immune checkpoint inhibitors as part of first-line therapy, immune checkpoint inhibitors are the preferred salvage therapy, with a response rate of approximately 20%, an overall survival of 12 to 13 months, and a favorable toxicity profile. In patients who have received prior checkpoint inhibitor therapy, docetaxel (75 mg/m^2 every 3 weeks) improves survival compared with best supportive care or first-generation cytotoxic agents. Ramucirumab, a monoclonal antibody against VEGFR2 receptor, in combination with docetaxel provides a modest improvement in overall survival. Compared with docetaxel, pemetrexed has similar efficacy as salvage therapy and a more favorable toxicity profile, but its use is restricted to patients with nonsquamous histology. Overall, current salvage therapy options are associated with response rates of less than 10%, with a median progression-free survival of 3 months and overall survival of 8 months. Combinations of cytotoxic or targeted agents have not resulted in improved survival and are not recommended for salvage therapy.

Management of Special Populations of Patients

In the United States, the median age at diagnosis of lung cancer is 70 years, and elderly patients represent a growing subset of lung cancer patients. Aging is associated with a lower tolerance for systemic therapy, thereby making current physical function and prospective quality-of-life considerations important factors in the choice of systemic treatment.

For patients with a targetable mutation, appropriate targeted therapy can be administered regardless of the performance status in view of the greater potential for benefit. The use of immune checkpoint inhibitors, guided by PD-L1 expression level, is also appropriate for this patient population. However, bevacizumab is associated with a narrow therapeutic index in nonsquamous cancers in older patients, and it is recommended only with great caution.

Platinum-based combinations are superior to single-agent therapy for patients with a good performance status. Nevertheless, single-agent chemotherapy has a survival benefit compared with supportive care in elderly patients and is often more appropriate for selected patients with a poor performance status.

Small Cell Lung Cancer

For small cell lung cancer, the role of surgery is limited to the less than 5% of patients who present with peripheral lung lesions without mediastinal nodal involvement. Surgery may also be useful in the 10 to 15% of patients whose SCLC has a mixed histology with features of NSCLC.

For patients with limited-stage SCLC, radiation therapy (70 Gy on a once-daily fractioned schedule or 45 Gy on a twice-daily schedule) in combination with chemotherapy can achieve cure for approximately 20 to 30% of patients.[18] Earlier initiation of radiation therapy appears superior to a delayed approach, and twice-daily radiation therapy fractions are better than once-daily. Prophylactic cranial irradiation is associated with a modest improvement in 5-year survival for patients who have limited-stage SCLC and who achieve complete remission after combined modality therapy.

TABLE 177-4 SYSTEMIC THERAPY REGIMENS IN ADVANCED SMALL CELL LUNG CANCER

FIRST-LINE THERAPY	SECOND-LINE THERAPY
Cis- or carboplatin/etoposide	Platinum rechallenge
Cis- or carboplatin/irinotecan	Topotecan
Cis- or carboplatin/etoposide/durvalumab	Irinotecan
Carboplatin/etoposide/atezolizumab	Lurbinoctedin
	Nivolumab
	Pembrolizumab

However, approximately two thirds of patients present with extensive-stage SCLC, defined as having metastatic disease outside of the chest or having large-volume intrathoracic disease that cannot be cured with surgery or treated with radiation therapy.[19] SCLC is characterized by excellent initial sensitivity to systemic chemotherapy, although the disease commonly recurs regardless of the extent of the initial response.

Four to six cycles of cisplatin and etoposide under expert supervision is the standard chemotherapy. Carboplatin is an acceptable alternative in the treatment of extensive-stage disease. The addition of four to six cycles of immune checkpoint inhibitors (e.g., durvalumab, atezolizumab, and serplulimab) results in modest improvement in overall survival,[A25,A26] but disease recurs at a median of 4 to 6 months (Table 177-4).

Disease that progresses during or within 90 days of administration of cisplatin-based chemotherapy is referred to as refractory relapse. Topotecan can provide a response rate of 20% and improve the symptom profile but not overall survival in randomized studies. The combination of cisplatin, etoposide, and irinotecan can significantly improve overall survival compared with topotecan alone but with a higher incidence of febrile neutropenia.[A27] Other agents under study include lurbinectedin, which demonstrated a response rate of 35% in a phase 2 study of patients with relapsed/refractory SCLC.[20]

Surveillance and Follow-Up

The importance of smoking cessation cannot be overemphasized, given the high risk of enhanced complications of chemotherapy and the higher incidence of second primary tumors in lung cancer survivors. Patients should be provided with counseling and behavioral therapy and other treatment modalities to assist their efforts to discontinue smoking (Chapter 363).

CT scans are commonly used to follow patients who undergo surgical resection or chemoradiotherapy, but the relative merits of CT scan versus chest radiography, the frequency of evaluation, and the role of PET scans are unclear. For patients with advanced-stage disease, CT scans are used to assess response to therapy after every two or three cycles of treatment. In view of the proven role for salvage therapy, patients who are in follow-up after combination chemotherapy should be closely observed for development of new symptoms or clinical deterioration in addition to periodic radiographic studies.

Supportive Care

Respiratory therapy should be offered and strongly recommended to patients with dyspnea after surgery or chemoradiotherapy. Because a high proportion of these patients also have smoking-related pulmonary diseases, referral to a pulmonologist should be considered in symptomatic patients. Overall, a team approach that includes supportive care personnel, oncologic psychiatrists, nutritionists, oncologists, and appropriate additional specialists should be used to ensure the return of lung cancer survivors to normalcy to the fullest extent possible.

Because the cure rate for lung cancers is only 16%, even in the most advanced health care systems, early discussion and institution of palliative and supportive care (Chapter 3) are therefore critical to maximize quality of life. The early integration of supportive care not only helps maintain and improve quality of life but also may produce a meaningful impact on overall survival. Among family members of elderly patients who died with advanced-stage lung cancer, perceptions of better end-of-life care were associated with earlier enrollment in hospice care, avoidance of ICU admissions, death outside the hospital, and advanced care planning consistent with patients' preferences.

PREVENTION

Primary Prevention

Primary prevention of lung cancer focuses on ways to prevent individuals from smoking and promotion of smoking cessation (Chapter 363), which remain the most effective means to prevent lung cancer. The Environmental Protection Agency recommends that the household radon level be less than 4 picocuries/liter of air, and simple remedial methods are available to reduce radon exposures above this threshold. Trials of supplemental β-carotene, vitamin E, and selenium have been unsuccessful.

Secondary Prevention

Screening with annual low-dose CT scans in high-risk individuals is associated with a 20% reduction in lung cancer mortality and a 6.7% reduction in all-cause mortality. Nearly 80% of patients diagnosed with lung cancer with low-dose CT have stage I, II, or IIIA disease amenable to curative therapy. Among patients with a positive CT scan, 96.4% are deemed false positive after additional evaluation.[A28] Screening with low-dose CT is most beneficial among patients who are at highest risk and prevents very few deaths among those at lowest risk. These results have led to the adoption of low-dose CT for early detection of lung cancer by major health organizations, including the U.S. Preventive Services Task Force.[21] Because overly frequent screening has associated harms, increasing the interval between screens in persons with a negative low-dose CT result might be warranted.

PROGNOSIS

The use of targeted therapies has resulted in a substantial 50% decline in the annual mortality rate among patients diagnosed with NSCLC, and such patients now have a 35% chance of dying from a cause other than lung cancer.[22] Adenocarcinoma in situ and minimally invasive adenocarcinoma have a more than 95% 5-year survival rate when they are treated with surgical resection, thereby making the establishment of a precise pathologic diagnosis of great significance. Large cell carcinoma is often associated with an aggressive clinical course and poor survival rates, even when it is found in the setting of early-stage disease.

For SCLC, the median survival of untreated extensive-stage disease is less than 2 months, but platinum-based chemotherapy results in response rates of 50 to 70% and a median survival of 9 to 11 months. Survival for SCLC has not changed considerably over the past two decades.

OTHER PULMONARY NEOPLASMS

MALIGNANT MESOTHELIOMA

Malignant pleural mesotheliomas are generally related to asbestos exposure, with a peak risk for developing the disease 30 to 35 years after the initial exposure. Additional possible risk factors include radiation and the SV40 virus.

Mesothelioma is generally diagnosed in the fifth to seventh decade of life (median age 60 years), with a male-to-female preponderance of 5 : 1. Common symptoms include dyspnea (60%) and chest wall pain or discomfort (60%).

Chest radiographs and CT scan usually reveal pleural thickening (Fig. 86-6). Tumor progression and symptoms are generally the result of local progression, and symptomatic distant metastases are a late occurrence. Cytologic evaluation of pleural fluid to establish diagnosis is difficult and often inaccurate. The diagnosis is generally made by a biopsy procedure under CT guidance or thoracoscopically, including VATS if necessary. Several staging systems have been proposed, but none has achieved complete acceptance.

TREATMENT AND PROGNOSIS

Treatment, depending on the extent of disease, commonly includes surgery (thoracoscopy with sclerosis, pleurectomy, extrapleural pneumonectomy), radiation therapy, and, often, chemotherapy.[23] With rare exceptions, no single modality has significantly improved survival rates, and neither chemotherapy nor radiation therapy provides long-term palliation or relief of symptoms. Combination chemotherapy with pemetrexed and cisplatin can provide symptomatic relief in patients with advanced, unresectable malignant mesothelioma.

Immunotherapy with nivolumab[A29] or with nivolumab plus ipilimumab[A30] can improve overall survival, and the combination of chemotherapy with immune checkpoint inhibition has yielded promising results. The addition of bevacizumab to pemetrexed plus cisplatin can improve overall survival but just from 16.1 to 18.8 months and at the cost of manageable toxic effects.[A31]

NEUROENDOCRINE AND OTHER LUNG TUMORS

Carcinoid Tumors

Carcinoid tumors (Chapter 213) of the lung account for 1 to 2% of all lung neoplasms. These neuroendocrine tumors trace their origin to the Kulchitsky cell present in bronchial epithelium. Typical and atypical carcinoids differ in the number of mitoses (<2 per 10 high-power fields vs. 2 to 10 per 10 high-power fields, respectively), nuclear pleomorphism (absent vs. present), and regional lymph node metastases (5 to 15% vs. 20 to 28%). Distant metastases at initial evaluation are unusual (<20%). Carcinoid tumors are not associated with cigarette smoking, are twice as common in women as in men, usually occur in patients younger than age 40 years, and arise in the perihilar area of the lung. Treatment of bronchial carcinoid tumors is based on the stage of the disease. Mediastinal staging is usually followed by surgical resection. With mediastinal lymph node involvement, radiation therapy is recommended for typical carcinoid tumors if surgery cannot be performed. For atypical carcinoid or metastatic disease, chemotherapy (etoposide plus cisplatin every 3 weeks for four cycles) plus radiation therapy is commonly used, but there is no evidence for the benefit of one therapy over another. Patients with typical or low-grade carcinoid tumors usually live for many years, with a 10-year survival of >90%, whereas patients with atypical carcinoid tumors have a 5-year survival rate of about 60 to 90%.

Large Cell Neuroendocrine Carcinoma

Large cell neuroendocrine carcinoma is an aggressive neuroendocrine tumor that does not meet the criteria for carcinoid, atypical carcinoid, or SCLC. Treatment is usually with platinum agents and etoposide under expert supervision.

Salivary Gland Carcinomas

Salivary gland carcinomas (Chapter 176) include mucoepidermoid carcinoma and adenoid cystic carcinoma, which represent approximately 0.2% of lung cancers. These slow-growing neoplasms arise from the bronchial glands and are usually treated with surgery.

Primary Lung Sarcoma and Lymphoma

Primary sarcomas of the lung are very rare and include malignant fibrous histiocytoma, fibrosarcoma, leiomyosarcoma, rhabdomyosarcoma, epithelioid hemangioendothelioma, angiosarcoma, and liposarcoma (Chapter 187). The primary treatment is surgery. Depending on the size and grade of the tumor and whether the margins are clear, radiation therapy or chemotherapy may also be given. A subset of sarcomatoid carcinoma of the lung is likely to harbor MET 14 exon skipping mutations that could be amenable to targeted therapy.

Primary lymphomas of the lung are also very rare, accounting for approximately 0.3% of all primary lung cancers. The most common type is a low-grade small lymphocytic lymphoma, for which surgery and chemotherapy are the usual treatments (Chapter 171).

178 NEOPLASMS OF THE ESOPHAGUS AND STOMACH

ADAM J. BASS AND ANIL K. RUSTGI

NEOPLASMS OF THE ESOPHAGUS

DEFINITION

The esophagus (Chapter 124) is a hollow tubular organ with primary physiologic functions related to contraction to permit propulsion of solid and liquid food contents into the stomach. The mucosa is a stratified squamous epithelium that covers the submucosa and muscle; the latter is skeletal muscle in the proximal esophagus and smooth muscle in the mid-distal esophagus. Cancers of the esophagus may be classified broadly into epithelial versus nonepithelial cancers. Benign epithelial tumors are referred to as squamous cell papillomas. Malignant epithelial tumors are classified into two main subtypes: esophageal squamous cell carcinoma and esophageal adenocarcinoma. Other, less common, esophageal epithelium-derived cancers include verrucous squamous cell carcinoma, adenosquamous carcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma. Benign nonepithelial tumors include leiomyoma, granular cell tumors, fibrovascular polyp, hemangioma, lymphangioma, lipoma, and fibroma. Malignant nonepithelial tumors include leiomyosarcoma and other sarcomas, metastatic carcinoma (e.g., originating from breast or lung), and lymphoma.

ESOPHAGEAL SQUAMOUS CELL CARCINOMA

EPIDEMIOLOGY

Esophageal squamous cell carcinoma is the more common type of esophageal cancer worldwide and is a major cause of cancer-related mortality.[1] Esophageal squamous cell carcinoma may have rates of up to 100 per 100,000 population in what is often termed the *Central Asian belt*, including regions around the Caspian Sea, Iran, India, and China; other areas of high incidence include some Mediterranean countries and Eastern Africa. In the United States, esophageal squamous cell carcinoma is more common among Black males than White males, with risks of 15.1 per 100,000 compared with 2.9 per 100,000, respectively. Rates are 2 to 3 times higher in men than in women. Although the U.S. incidence of esophageal squamous cell carcinoma is low in both men and women younger than age 50 years, the incidence increases with advancing age.

Risk Factors

Hereditary esophageal squamous cell carcinoma is exceedingly rare, and is associated with a desquamating condition termed *tylosis palmaris et plantaris*. This desquamation most dramatically affects the hands and feet but extends to the esophagus as well. Another uncommon condition, Plummer-Vinson syndrome or Paterson-Brown Kelly syndrome, entails glossitis, cervical esophageal webs, and iron deficiency anemia. In both conditions, it is likely that chronic inflammation triggers the cascade of events that culminate in esophageal squamous dysplasia and esophageal squamous cell carcinoma.

Most esophageal squamous cell carcinoma cases are related to cigarette smoking or alcohol consumption, especially in combination, because their deleterious effects appear to be synergistic. Chemical carcinogens that are present in both include *N*-nitroso compounds, polycyclic aromatic hydrocarbons, and aromatic amines. The relative risk for esophageal squamous cell carcinoma is 6.2-fold higher in persons who smoke more than 25 cigarettes daily. Cessation of cigarette smoking is helpful in attenuating risk after 10 years of abstinence. Cigarette smokers who drink beer and whiskey have a 10- to 25-fold enhanced risk of developing esophageal squamous cell carcinoma. Vitamins A, B_{12}, C, and E; folic acid; and certain minerals (zinc, selenium, molybdenum) exert direct or indirect antioxidant effects, and their deficiencies impair epithelial and tissue homeostasis and regeneration.

Other risk factors for esophageal squamous cell carcinoma (Table 178-1) include achalasia (Chapter 124), which is a disorder that involves aganglionosis of the Auerbach plexus, thereby resulting in dysphagia, chest pain, and weight loss, among other symptoms. The emergence of esophageal squamous cell carcinoma may be observed 10 to 20 years after the identification of achalasia. Because head and neck squamous cell carcinoma (Chapter 176) shares many of the same environmental and lifestyle risk factors with esophageal squamous cell carcinoma, particularly alcohol use and tobacco smoking, head and neck squamous cell carcinoma and esophageal squamous cell carcinoma may occur synchronously or metachronously. In different parts of the world, esophageal

178 NEOPLASMS OF THE ESOPHAGUS AND STOMACH

ADAM J. BASS AND ANIL K. RUSTGI

NEOPLASMS OF THE ESOPHAGUS

DEFINITION

The esophagus (Chapter 124) is a hollow tubular organ with primary physiologic functions related to contraction to permit propulsion of solid and liquid food contents into the stomach. The mucosa is a stratified squamous epithelium that covers the submucosa and muscle; the latter is skeletal muscle in the proximal esophagus and smooth muscle in the mid-distal esophagus. Cancers of the esophagus may be classified broadly into epithelial versus nonepithelial cancers. Benign epithelial tumors are referred to as squamous cell papillomas. Malignant epithelial tumors are classified into two main subtypes: esophageal squamous cell carcinoma and esophageal adenocarcinoma. Other, less common, esophageal epithelium-derived cancers include verrucous squamous cell carcinoma, adenosquamous carcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma. Benign nonepithelial tumors include leiomyoma, granular cell tumors, fibrovascular polyp, hemangioma, lymphangioma, lipoma, and fibroma. Malignant nonepithelial tumors include leiomyosarcoma and other sarcomas, metastatic carcinoma (e.g., originating from breast or lung), and lymphoma.

ESOPHAGEAL SQUAMOUS CELL CARCINOMA

EPIDEMIOLOGY

Esophageal squamous cell carcinoma is the more common type of esophageal cancer worldwide and is a major cause of cancer-related mortality.[1] Esophageal squamous cell carcinoma may have rates of up to 100 per 100,000 population in what is often termed the *Central Asian belt*, including regions around the Caspian Sea, Iran, India, and China; other areas of high incidence include some Mediterranean countries and Eastern Africa. In the United States, esophageal squamous cell carcinoma is more common among Black males than White males, with risks of 15.1 per 100,000 compared with 2.9 per 100,000, respectively. Rates are 2 to 3 times higher in men than in women. Although the U.S. incidence of esophageal squamous cell carcinoma is low in both men and women younger than age 50 years, the incidence increases with advancing age.

Risk Factors

Hereditary esophageal squamous cell carcinoma is exceedingly rare, and is associated with a desquamating condition termed *tylosis palmaris et plantaris*. This desquamation most dramatically affects the hands and feet but extends to the esophagus as well. Another uncommon condition, Plummer-Vinson syndrome or Paterson-Brown Kelly syndrome, entails glossitis, cervical esophageal webs, and iron deficiency anemia. In both conditions, it is likely that chronic inflammation triggers the cascade of events that culminate in esophageal squamous dysplasia and esophageal squamous cell carcinoma.

Most esophageal squamous cell carcinoma cases are related to cigarette smoking or alcohol consumption, especially in combination, because their deleterious effects appear to be synergistic. Chemical carcinogens that are present in both include *N*-nitroso compounds, polycyclic aromatic hydrocarbons, and aromatic amines. The relative risk for esophageal squamous cell carcinoma is 6.2-fold higher in persons who smoke more than 25 cigarettes daily. Cessation of cigarette smoking is helpful in attenuating risk after 10 years of abstinence. Cigarette smokers who drink beer and whiskey have a 10- to 25-fold enhanced risk of developing esophageal squamous cell carcinoma. Vitamins A, B_{12}, C, and E; folic acid; and certain minerals (zinc, selenium, molybdenum) exert direct or indirect antioxidant effects, and their deficiencies impair epithelial and tissue homeostasis and regeneration.

Other risk factors for esophageal squamous cell carcinoma (Table 178-1) include achalasia (Chapter 124), which is a disorder that involves aganglionosis of the Auerbach plexus, thereby resulting in dysphagia, chest pain, and weight loss, among other symptoms. The emergence of esophageal squamous cell carcinoma may be observed 10 to 20 years after the identification of achalasia. Because head and neck squamous cell carcinoma (Chapter 176) shares many of the same environmental and lifestyle risk factors with esophageal squamous cell carcinoma, particularly alcohol use and tobacco smoking, head and neck squamous cell carcinoma and esophageal squamous cell carcinoma may occur synchronously or metachronously. In different parts of the world, esophageal

ABSTRACT

Esophageal and gastric cancers are common worldwide. Esophageal cancer is subtyped into esophageal squamous cell carcinoma and esophageal adenocarcinoma, the latter of which is preceded typically by Barrett esophagus. The most common subtypes of gastric cancer are gastric adenocarcinoma followed by lymphoma. The pathobiology (especially genetics), clinical presentation, staging, diagnostic strategies, and therapeutic options often are different with each of these malignancies.

KEYWORDS

esophageal cancer

Barrett esophagus
esophageal adenocarcinoma
gastric cancer
gastric adenocarcinoma
lymphoma

squamous cell carcinoma is also associated with chronic esophageal stricture due to lye ingestion, consumption of maté (a hot herb-based beverage), celiac sprue, infection with human papillomavirus (HPV) (especially genotypes HPV-16, HPV-18, and HPV-33), and radiation injury.

PATHOBIOLOGY

Esophageal squamous cell carcinoma involves the transition from normal squamous epithelium to squamous dysplasia to cancer. The initiation, progression, and metastatic potential of esophageal squamous cell carcinoma are associated with a number of genetic alterations, including overexpression of epidermal growth factor receptor (*EGFR*) and cyclin D1 oncogenes, as well as inactivation of *TP53*, *p16INK4A*, and p120-catenin (*p120ctn*) tumor suppressor genes. The frequency of these changes varies greatly based upon various studies, but the oncogenic alterations generally appear early in dysplasia and early esophageal squamous cell carcinoma, whereas the inactivation of tumor suppressor genes appears as later events in established primary and metastatic esophageal squamous cell carcinoma. From a genomic viewpoint, the SOX-2 transcription factor, which is important in the pluripotent capacity of somatic cells, is an important gene involved in the pathogenesis of esophageal squamous cell carcinoma. Conditional knockout of the *p120ctn* tumor suppressor gene in the esophagus of mice results in invasive esophageal squamous cell carcinoma. Deep DNA sequencing has confirmed these genetic alterations and revealed a lower frequency of other alterations, such as inactivation of chromatin-modifying enzymes.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Although esophageal squamous dysplasia is typically not associated with symptoms, esophageal squamous cell carcinoma, which has a predilection for the proximal to mid-esophagus, may be associated with dysphagia, odynophagia, atypical or typical chest pain, gastrointestinal bleeding, nausea, vomiting, weight loss, and malnutrition. Esophageal squamous cell carcinoma may metastasize to local lymph nodes, lung, liver, and bone. Symptoms attributable to metastatic esophageal squamous cell carcinoma may include bone-related pain, dyspnea, and evidence of jaundice and liver failure, depending upon the extent of metastatic disease.

Physical Examination

Weight loss may result in general cachexia and muscle wasting. The patient should be evaluated for changes in hair, skin integrity, and nail beds as a reflection of malnutrition. Lymphadenopathy may be detected in the anterior cervical and supraclavicular regions. Hepatomegaly and complications of liver disease may herald metastatic disease to the liver.

Laboratory Studies

A progressive iron deficiency anemia may be due to chronic indolent upper gastrointestinal bleeding. Additional abnormalities may be reflected in metabolic disturbances, such as metabolic alkalosis due to vomiting and hypernatremia due to dehydration. Liver enzyme abnormalities, both hepatocellular and cholestatic, may reflect metastasis to the liver. Paraneoplastic hypercalcemia is uncommon. Esophageal squamous cell carcinoma has no specific markers, but an elevated carcinoembryonic antigen (CEA) level and levels of cell-free DNA from tumor cells may be used to aid in monitoring for recurrent disease after therapy.

DIAGNOSIS

An upper gastrointestinal contrast radiographic study can show a filling defect due to the mucosal lesion or impaired transit of contrast due to luminal growth (Chapter 119). However, definitive diagnosis involves direct visualization with upper endoscopy (Chapter 120). Once the mass is visualized, biopsies are necessary to confirm the diagnosis and to enable genomic studies. Fine-needle aspiration can provide a rapid diagnostic assessment in the procedure room. Esophageal squamous cell carcinoma may involve local lymph nodes, which are best detected by endoscopic ultrasound; as needed, samples can then be analyzed by cytopathology following fine-needle aspiration. Endoscopic ultrasound is routinely used also to gauge depth of invasion, which guides the use of neoadjuvant therapy in node-negative localized cases.

Evaluation of metastatic disease involves chest and abdominal computed tomography (CT) scans. Bone scan might be useful in patients who are symptomatic with bone-related pain. Positron emission tomography (PET) is increasingly used to assess metastatic disease. In totality, these diagnostic modalities also allow for staging of esophageal squamous cell carcinoma, which is important in guiding therapeutic options.

TREATMENT

Surgical Therapy

Surgery is the cornerstone of therapy for curative intent, but adjuvant chemotherapy or chemoradiation markedly improves outcomes.[2] Depending upon the location of the esophageal squamous cell carcinoma, either total esophagectomy or subtotal esophagectomy is pursued.[3] For the latter, jejunal or colonic interposition can be done.

Surgical techniques include transthoracic, transhiatal, and radical en bloc resections. Increasing surgical proficiency in performing esophagectomy improves short-term as well as long-term mortality results in esophageal cancer. In selected patients, minimally invasive esophagectomy[4] can provide equivalent or better perioperative mortality, morbidity, and oncologic outcomes compared with open surgery.[A1–A3]

In patients who are medically unfit for surgery or in whom surgery is likely to result in high morbidity (e.g., tumors in the cervical esophagus), definitive chemoradiation is often pursued as an alternative to surgical therapy. Salvage esophagectomy after definitive chemoradiotherapy can offer acceptable short- and long-term outcomes in selected patients whose esophageal cancers are treated at experienced centers.

Medical Therapy

Neoadjuvant or adjuvant combination chemoradiotherapy under expert supervision is more effective than surgery alone for improving the survival of patients with resectable esophageal cancer.[A4] For patients who have localized node-positive or more advanced esophageal cancer, outcomes are improved by neoadjuvant chemoradiation with about 40 Gy of radiation plus either carboplatin with paclitaxel[A5] or cisplatin with vinorelbine.[A6] Adjuvant nivolumab can enhance survival in patients who have residual disease despite chemoradiation and surgery.

In patients who have metastatic esophageal squamous cell carcinoma, first-line platinum-containing cytotoxic chemotherapy should be combined with immune checkpoint inhibition using nivolumab,[A7,A8] camrelizumab,[A9] toripalimab,[A10] or pembrolizumab.[A11] For patients who have unresectable or metastatic disease, palliative therapy includes endoscopically placed expandable prosthetic stents (to open the nearly obstructed lumen and to allow passage of food contents), percutaneous endoscopic gastrotomy tubes (to deliver nutrition to the stomach distal to the mass lesion), total parenteral nutrition, pain control, and systemic chemotherapy.[5]

PROGNOSIS

The 5-year survival for treated esophageal squamous cell carcinoma is dependent upon stage and types of therapies used. For stages T1 and T2 without lymph node involvement, surgery alone may be curative in more than 60% of cases. Major postoperative complications, which occur in about one third of patients, exert a long-lasting negative effect on health-related quality of life in patients who survive for 5 years after esophagectomy for cancer. Dyspnea, fatigue, eating restrictions, sleep difficulty, and gastroesophageal reflux progressively worsen more during follow-up in patients who suffer such major postoperative complications compared with patients without major surgical complications.

ESOPHAGEAL ADENOCARCINOMA

EPIDEMIOLOGY

Esophageal adenocarcinoma has an age-adjusted annual incidence of 1.3 per 100,000. It affects Whites more than Blacks, males much more than females (3:1 to 5.5:1), and increases in incidence after age 40 years. The incidence of esophageal adenocarcinoma is increasing dramatically in developed countries, especially in the United States (by 4 to 10% annually) and Western/Northern Europe.[6]

Risk Factors

Obesity (central) is an important risk factor for esophageal adenocarcinoma (see Table 178-1), perhaps because it is related to either mechanical factors that foster greater gastroesophageal reflux disease (GERD) or, more likely, the release of proinflammatory adipokines, cytokines, and chemokines that track to the esophagus. The major recognized precursor of esophageal adenocarcinoma is Barrett esophagus (Chapter 124), which is the replacement of

the normal stratified squamous epithelium by an incomplete small intestinal epithelium (metaplasia) that projects from the gastroesophageal junction into the distal esophagus in a distal-proximal gradient (Chapter 124). In turn, Barrett esophagus is fostered by GERD as well as by an admixture of bile acids in the acid refluxate. A small subset of patients with Barrett esophagus may progress to esophageal adenocarcinoma through intermediate stages of low-grade and high-grade dysplasia. In Barrett esophagus, one case of esophageal adenocarcinoma is estimated to arise in every 55 to 441 patient-years, a rate that corresponds to an approximately 125-fold increased risk for esophageal adenocarcinoma compared with the risk in the general population.

PATHOBIOLOGY

In Barrett esophagus, metaplasia in the distal esophagus results in a small intestinal epithelium with columnar enterocytes and secretory goblet cells, but without Paneth cells or enteroendocrine cells—hence the designation of incomplete intestinal metaplasia.[7] By itself, the metaplasia of Barrett esophagus cannot become esophageal adenocarcinoma. However, if and when Barrett esophagus transitions to low-grade and high-grade dysplasia, risk for esophageal adenocarcinoma increases dramatically. Barrett esophagus is associated with abnormal DNA ploidy as well as genetic alterations in epidermal growth factor receptor signalling, *TP53*, and *p16INK4A*. Emerging data demonstrate that markers, including mutation of TP53 and detection of aneuploidy, can identify patients whose Barrett esophagus has the greatest risk of progressing to cancer.

Esophageal adenocarcinoma can be distinguished from gastroesophageal adenocarcinomas (so-called gastroesophageal junctional cancer) and gastric cardia adenocarcinomas based on its location, although genomic data demonstrate remarkable similarity between esophageal and gastric adenocarcinomas. Whole-genome approaches show gains and losses of chromosomal regions that might lead to identification of known and previously unknown genes critical in the pathogenesis of esophageal adenocarcinoma.

CLINICAL MANIFESTATIONS

Symptoms and Signs

A small subset (about 5 to 15%) of patients who have gastroesophageal reflux disease may develop Barrett esophagus. However, millions of people are affected with gastroesophageal reflux disease, and most patients who have gastroesophageal reflux disease do not undergo upper endoscopy. Patients with Barrett esophagus may or may not have symptoms related to gastroesophageal reflux disease. Chronic gastroesophageal reflux disease with Barrett esophagus may be associated with distal esophageal strictures. Patients with esophageal adenocarcinoma may suffer from dysphagia, odynophagia, upper gastrointestinal bleeding, chest pain, nausea, vomiting, early satiety, weight loss, and malnutrition.

Physical Examination

Examination of the patient may reveal signs consistent with malnutrition and weight loss. Hepatomegaly may be present, and lymphadenopathy may be a sign of metastasis. Paraneoplastic syndromes are unusual with esophageal adenocarcinoma.

Laboratory Studies

Patients with esophageal adenocarcinoma may have iron deficiency anemia (from occult upper GI bleeding), metabolic derangements, and abnormal liver enzyme tests owing to metastatic disease. The CEA level may be elevated as a tumor serologic marker, although it is not a diagnostic test.

DIAGNOSIS

It is important to ensure that esophageal adenocarcinoma is not mistaken for a benign entity such as a primary esophageal motility disorder. Barium swallow radiography may lead to the suspicion of Barrett esophagus and can diagnose luminal mass lesions consistent with esophageal adenocarcinoma in the distal esophagus. However, the mainstay of diagnosis is upper endoscopy. If the extent of Barrett esophagus is 3 cm or less, it is termed *short-segment Barrett esophagus*; if it is more than 3 cm, it is referred to as *long-segment Barrett esophagus*. This distinction is important because the risk for esophageal adenocarcinoma in long-segment Barrett esophagus is greater than in short-segment Barrett esophagus. Unlike the pinkish-white hue of the normal esophageal mucosa, esophageal adenocarcinoma has a characteristic salmon-colored mucosa that can be visualized at the gastroesophageal junction, with frondlike projections in a proximal direction. Endoscopic mucosal biopsies from the Barrett esophagus region (with control biopsies from the normal esophagus and gastric cardia) are required for histopathologic diagnosis. Features of dysplasia are best appreciated in the absence of reflux-related esophagitis, which can lead to nuclear architectural distortion. Hence, gastric acid production should be suppressed with proton pump inhibitor therapy (Table 124-1) for 6 to 8 weeks prior to biopsy.

TREATMENT

The principles for surgical resection and neoadjuvant therapy after chemoradiation and surgical resection are similar to what is recommended for squamous cell esophageal carcinoma. However, the impact of neoadjuvant chemoradiation is more modest in esophageal adenocarcinoma. In the setting of residual disease despite chemoradiation and surgery, adjuvant nivolumab can improve survival.[A12]

Systemic therapies for advanced and metastatic esophageal adenocarcinomas are analogous to what are recommended for adenocarcinomas of the stomach, including immune checkpoint therapies in concert with chemotherapy for first-line treatment under expert supervision. For tumors that overexpress the HER2 protein, targeted therapies are recommended under expert oversight. Patients with esophageal cancers often have serious comorbid conditions (e.g., obesity, heart disease, emphysema, and malnutrition) that limit treatment options after first-line therapy. For advanced, unresectable tumors, self-expanding stents, often with localized brachytherapy, can provide palliation.[8]

PREVENTION

If the patient has Barrett esophagus metaplasia, upper endoscopy should be repeated every 3 years. However, low-grade dysplasia (with confirmation by an expert pathologist) requires surveillance endoscopy every 6 to 12 months. High-grade dysplasia, if properly evaluated by the pathologist, may require reconfirmation, but then leads to either medical (radiofrequency ablation or endoscopic mucosal resection) or surgical intervention because of the possibility of missed contiguous esophageal adenocarcinoma (Chapter 124). Radiofrequency ablation reduces the progression of low-grade dysplasia or possibly high-grade Barrett esophageal dysplasia to cancer. Endoscopic mucosal resection is used for Barrett esophagus–related high-grade dysplasia or Barrett esophagus associated with intramucosal (tumor stage T1a) esophageal adenocarcinoma.[9] Endoscopic ultrasound may be helpful in discriminating between high-grade dysplasia and esophageal intramucosal adenocarcinoma.

PROGNOSIS

Localized disease detected by careful follow-up of patients with residual Barrett esophagus can be cured. With localized disease, long-term survival can exceed 50%, with higher rates among patients with complete responses to neoadjuvant therapy. However, esophageal adenocarcinoma carries among the most dismal survival rates within oncology. The overall 5-year survival is about 20%, because the disease is diagnosed at an advanced stage, it has a propensity to relapse after surgical therapy, and the efficacy of chemoradiation is modest. Whether adjuvant immune checkpoint therapy and the introduction of new agents will substantially improve survival remains to be proven.

NEOPLASMS OF THE STOMACH

DEFINITION

Gastric neoplasms are predominantly malignant, and nearly 90 to 95% of these tumors are adenocarcinomas. Less frequently observed malignant diseases include lymphomas, especially non-Hodgkin lymphoma, and sarcomas such as leiomyosarcoma. Benign gastric neoplasms include leiomyomas, carcinoid tumors, and lipomas.

ADENOCARCINOMA OF THE STOMACH

EPIDEMIOLOGY

The great geographic variation in the incidence of gastric cancer worldwide indicates that environmental factors influence the pathogenesis of gastric carcinogenesis. Further support for this notion comes from observations that groups emigrating from high-risk to low-risk areas, such as Japanese individuals moving to Hawaii and Brazil, acquire the low risk of the area into which they emigrate, presumably because of adoption of the endogenous lifestyle and exposure to different environmental factors.[10]

TABLE 178-2 CONDITIONS PREDISPOSING TO OR ASSOCIATED WITH GASTRIC CANCER

ENVIRONMENTAL
Helicobacter pylori infection
Dietary: excess of salt (salted pickled foods), nitrates/nitrites, carbohydrates; deficiency of fresh fruit, vegetables, vitamins A and C, refrigeration
Low socioeconomic status
Cigarette smoking
GENETIC
Familial gastric cancer (rare)
Associated with hereditary nonpolyposis colorectal cancer
Blood group A
PREDISPOSING CONDITIONS
Chronic gastritis, especially atrophic gastritis with or without intestinal metaplasia
Pernicious anemia
Intestinal metaplasia
Gastric adenomatous polyps (>2 cm)
Postgastrectomy stumps
Gastric epithelial dysplasia
Ménétrier disease (hypertrophic gastropathy)
Chronic peptic ulcer

Gastric adenocarcinoma was the most frequently observed malignant disease in the world until the mid-1980s, and it remains extremely common among men in certain regions such as tropical South America, some parts of the Caribbean, and Eastern Europe. Regardless of gender, it remains one of the most common malignancies in Japan and China. Nevertheless, incidence is decreasing worldwide.[11,12]

Whereas gastric cancer was the most common cancer in the United States in the 1930s, its annual incidence has steadily decreased to fewer than 10,000 new cases per year. The U.S. incidence is about 1.8-fold higher in non-Whites and is highest among Korean Americans.[13] However, although the incidence of gastric adenocarcinoma localized to the distal stomach has declined, the incidence of proximal gastric and gastroesophageal junctional adenocarcinomas has been steadily increasing in the United States, a finding that perhaps reflects differences in pathogenic factors.

Typically, gastric cancer occurs between ages 50 and 70 years and is uncommon before age 30. The rates are higher in men than in women by 2:1. However, rates of the diffuse histologic form of gastric cancer are rising in younger women for reasons that are not understood. In the United States, gastric cancer is more common in Black men and women compared with White men and women.

Risk Factors

Risk factors for the development of gastric adenocarcinoma can be divided into environmental and genetic factors as well as precursor conditions (Table 178-2). For example, *Helicobacter pylori* infection is significantly more common in patients with noncardia gastric cancer than in matched control groups. Unlike distal gastric cancer emerging in the setting of intestinal metaplasia, where metaplasia is typically precipitated by *H. pylori*, adenocarcinomas near the gastroesophageal junction appear to be inversely associated with *H. pylori*. Epidemiologic studies of high-risk populations have also suggested that genotoxic agents such as *N*-nitroso compounds may play a role in gastric tumorigenesis. *N*-nitroso compounds can be formed in the human stomach by nitrosation of ingested nitrates, which are common constituents of the diet. High nitrate concentrations in soil and drinking water have been observed in areas with high death rates from gastric cancer. Atrophic gastritis (Chapter 125), with or without intestinal metaplasia, is observed in association with gastric cancer, especially in endemic areas. Pernicious anemia (Chapter 150) is associated with a several-fold increase in gastric cancer. Atrophic gastritis and intestinal metaplasia likely represent intermediary steps to gastric cancer. The achlorhydria associated with gastritis related to *H. pylori* infection, pernicious anemia, or other causes favors the growth of bacteria that are capable of converting nitrates to nitrites. At the same time, most patients with atrophic gastritis do not develop gastric cancer, a finding suggesting that neither atrophic gastritis nor achlorhydria alone is responsible.

Benign gastric ulcers do not appear to predispose patients to gastric cancer. However, patients who have a gastric remnant after subtotal gastrectomy for benign disorders have an increased relative risk for gastric cancer of 1.5 to 3.0 by 15 to 20 years after surgery.

PATHOBIOLOGY

Gastric adenocarcinomas can be divided into two types based on the Lauren classification[14]: intestinal and diffuse. The intestinal type (typically in the distal stomach with ulcerations and often preceded by premalignant lesions) is declining in incidence in the United States, but adenocarcinomas in the area of the cardia/gastroesophageal junction have increased. By contrast, the diffuse type involves widespread thickening of the stomach, especially in the cardia, and it often affects younger patients; this form may present as linitis plastica, which is a nondistensible stomach with the absence of folds and a narrowed lumen caused by infiltration of the stomach wall with tumor. Diffuse-type gastric cancers harbor mucin-producing cells. Other conditions that may result in linitis plastica include lymphoma (Chapter 171), tuberculosis (Chapter 299), syphilis (Chapter 295), and amyloidosis (Chapter 174).

Key histopathologic features of gastric cancer include the degree of differentiation, invasion through the gastric wall, lymph node involvement, and the presence or absence of signet ring cells within the tumor itself. Other pathologic manifestations include a polypoid mass, which may be difficult to distinguish from a benign polyp. Early gastric cancer, a condition that is common in Japan and has a relatively favorable prognosis, consists of superficial lesions with or without lymph node involvement. These lesions can be classified as group I, polypoid; group II, fungating ulcer with sharp raised margins; group III, ulcer with poorly defined infiltrative margins; and group IV, infiltrative, mostly intramural lesion, not well demarcated.

The leading hypothesis explaining the way in which *H. pylori* predisposes to gastric cancer risk is the induction of an inflammatory response, in which IL-1β may be pivotal. Chronic *H. pylori* infection also leads to chronic atrophic gastritis with resulting achlorhydria, which in turn favors bacterial growth that can convert dietary nitrates to nitrites. These nitrites, in combination with genetic factors, promote abnormal cellular proliferation, genetic mutations, and eventually cancer.

Genetics

Gastric cancer patients have a two- to three-fold higher family history of the disease, thereby suggesting a genetic contribution. Furthermore, germline or inherited mutations in the genes for E-cadherin and α-catenin, albeit rare, have been described in diffuse hereditary gastric cancer, which is seen in young patients. In addition, in Lynch syndrome (Chapter 179), patients have associated extracolonic cancers, including gastric cancer. Patients with familial adenomatous polyposis also have an increased risk of distal (antral) gastric adenocarcinoma. Blood group A is also associated with a higher incidence of gastric cancer, even in nonendemic areas.

Gene expression data have identified molecular subtypes linked to distinct patterns of molecular alterations that are associated with differences in disease progression and prognosis. Examples include Epstein-Barr virus–related tumors, tumors with microsatellite or chromosomal instability, and a diffuse histologic subtype that often has decreased genomic instability.[15] Gastric tumors with chromosomal instability bear striking similarity to esophageal adenocarcinomas. Both the activation of oncogenes and the inactivation of tumor suppressor genes can be promoted by processes including chromosomal instability, aberrant DNA methylation, and microsatellite instability. Loss of *p53* is common, especially in the chromosomal instability class of gastric cancers. The inactivation of *p53* in precancerous gastric lesions suggests that mutation of *p53* is an early event in gastric carcinogenesis.

CLINICAL MANIFESTATIONS

Symptoms and Signs

In its early stages, gastric cancer may be asymptomatic or produce only nonspecific symptoms that make early diagnosis difficult. Later symptoms include bloating, dysphagia, and epigastric pain. Early satiety or vomiting may suggest partial gastric outlet obstruction, although gastric dysmotility can contribute to the vomiting with nonobstructive tumors. Epigastric pain reminiscent of that associated with peptic ulcer occurs in about one fourth of patients, but the pain is not relieved by food or antacids in most patients with gastric cancer. Pain that radiates to the back may indicate that the tumor has penetrated the pancreas. When dysphagia is associated with gastric cancer, this symptom suggests a more proximal gastric tumor at the gastroesophageal junction or in the fundus.

Signs of gastric cancer include bleeding, which can result in iron deficiency anemia (Chapter 145) that produces weakness, fatigue, and malaise, as well as rare, more serious cardiovascular and cerebrovascular consequences. Perforation related to gastric cancer is unusual. Gastric cancer metastatic to the liver can lead to right upper quadrant pain, jaundice, and fever. Lung metastases can cause cough, hiccups, and hemoptysis. Peritoneal carcinomatosis can lead to malignant ascites unresponsive to diuretics. Gastric cancer can also metastasize to bone.

Physical Examination

In the earliest stages of gastric cancer, the physical examination may be unremarkable. At later stages, patients become cachectic, and an epigastric mass may be palpated. If the tumor has metastasized to the liver, hepatomegaly with jaundice and ascites may be present. Portal or splenic vein invasion and thrombosis can cause splenomegaly. Lymph node involvement in the left supraclavicular area is termed a Virchow node, and periumbilical nodal involvement is called a Sister Mary Joseph node. The fecal occult blood test may be positive. Metastasis to the ovary is termed Krukenberg tumor.

Paraneoplastic syndromes (Chapter 164) may precede or occur concurrently with gastric cancer. Examples include Trousseau syndrome (Chapter 67), which is recurrent migratory superficial thrombophlebitis indicative of a possible hypercoagulable state; acanthosis nigricans, which arises as raised and hyperpigmented skin lesions of the flexor areas, neck, axilla, groin, and mucosal membranes; neuromyopathy with involvement of the sensory and motor pathways; and central nervous system syndromes with altered mental status and ataxia.

Laboratory Studies

Laboratory studies may reveal iron deficiency anemia. Microangiopathic hemolytic anemia has also been reported. Abnormalities in liver tests generally indicate metastatic disease. Hypoalbuminemia is a marker of malnutrition. Protein-losing enteropathy is rare but can be seen in Ménétrier disease (Chapter 125), which is another predisposing condition. Serologic test results, such as CEA and CA72.4 (typically not used), may be abnormal. Although these tests are not recommended for initial diagnosis, they may be useful for monitoring disease after surgical resection.

DIAGNOSIS

The diagnostic accuracy of upper endoscopy with biopsy and cytologic examination approaches 95 to 99% for both types of gastric cancer. Cancer may arise as a small mucosal ulceration, a polyp, or a mass (Fig. 178-1). In some patients, gastric ulceration may first be noted in an upper gastrointestinal barium contrast study. A benign gastric ulcer is associated with a smooth, regular base, whereas a malignant ulcer is associated with a surrounding mass, irregular folds, and an irregular base. Although these and other radiographic characteristics historically helped to predict benign versus malignant disease, upper gastrointestinal endoscopy with biopsy and cytologic examination is mandatory whenever a gastric ulcer is found on a radiologic study, even if the ulcer has benign characteristics.

Endoscopic ultrasonography is very helpful in both the diagnosis and staging of gastric cancer. The extent of tumor, including gastric wall invasion and local lymph node involvement, can be assessed by endoscopic ultrasound (Fig. 178-2), which provides information complementary to that obtained from CT scans. Endoscopic ultrasound can help guide aspiration biopsies of lymph nodes to determine malignant involvement. CT of the chest, abdomen, and pelvis should be performed to document lymphadenopathy and extragastric organ (especially lung and liver) involvement. In some centers, staging of gastric cancer entails bone scans because of the proclivity of gastric cancer to metastasize to bone.

TREATMENT

Surgical Therapy

The primary chance for cure of gastric cancer is surgical resection, which is possible in 25 to 30% of cases.[16] If the tumor is confined to the distal stomach, subtotal gastrectomy is performed, with resection of lymph nodes in the porta hepatis and the pancreatic head. When early gastric cancer is confined to the mucosa, endoscopic mucosal resection may be an alternative. By contrast, tumors of the proximal stomach require total gastrectomy to obtain an adequate margin and to remove lymph nodes; distal pancreatectomy and splenectomy are usually also performed as part of this procedure, which carries higher mortality and morbidity rates. The addition of para-aorta nodal dissection does not improve survival. Even if a curative procedure is not possible because of metastasis, limited gastric resection may be necessary for patients with excessive bleeding or obstruction. However, gastrectomy followed by chemotherapy is no better than chemotherapy alone for advanced gastric cancer that is not surgically curable.[A13] If cancer recurs in the gastric remnant, limited resection may again be necessary for palliation. Most recurrences of either type of gastric cancer are in the local or regional area of the original tumor.

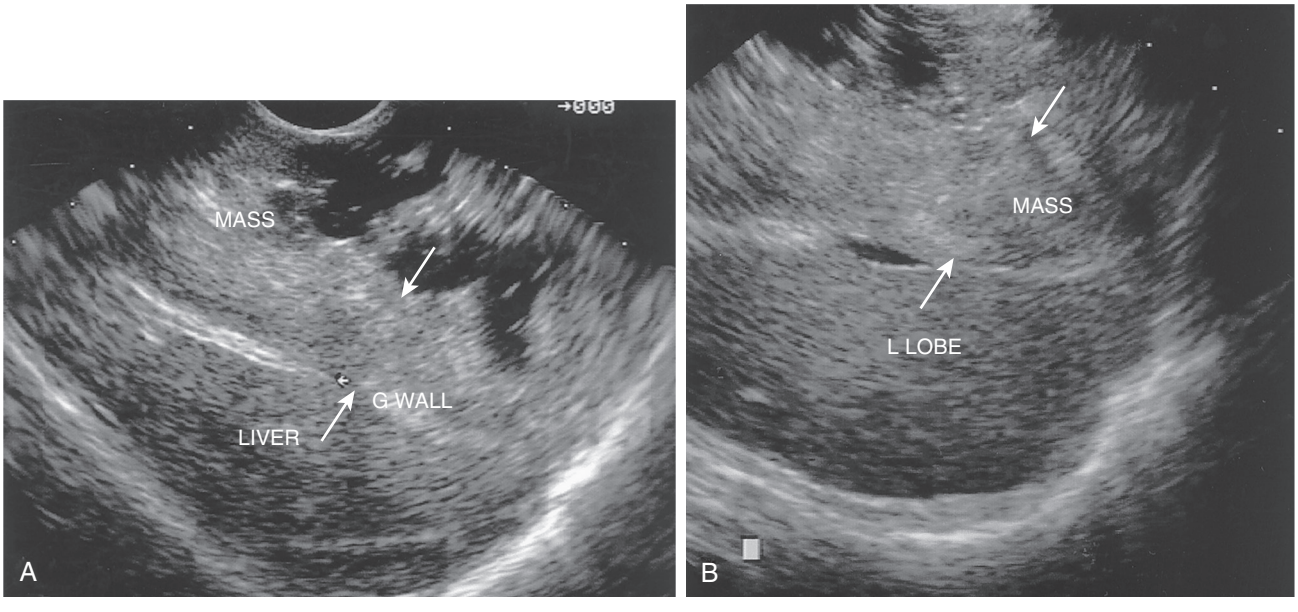

FIGURE 178-2. Gastric mass. Endoscopic ultrasonography depicting a large gastric mass that is compressing the liver and gallbladder wall (**A**) and, on a different view, the left lobe of the liver (**B**).

Medical Therapy

Gastric cancer is often responsive to chemotherapy.[17,18] Single-agent chemotherapy, which provides partial response rates of 20 to 30%, is reserved for patients with a poor performance status. Otherwise, combination chemotherapy increases overall survival compared with single-agent chemotherapy in metastatic disease as well as in the neoadjuvant and adjuvant treatment of nonmetastatic disease.[A14]

In patients who have gastric cancer and who undergo surgery with curative intent, the addition of perioperative chemotherapy can improve survival. For example, the combination of epirubicin, cisplatin, and fluorouracil, given both preoperatively and postoperatively, improves 5-year survival from 23 to 36% in patients with resectable gastroesophageal cancer. Perioperative therapy with a combination of fluorouracil, leucovorin, oxaliplatin, and docetaxel (Table 178-3) can extend median survival to 50 months and is increasingly used in medically fit patients.[A15] However, postoperative chemoradiotherapy does not improve overall survival compared with postoperative chemotherapy in patients whose resectable gastric cancers are treated with adequate preoperative chemotherapy and surgery.[A16]

For advanced or metastatic disease, combination regimens emphasize two-drug therapies, typically 5-fluorouracil or capecitabine with platinum. First-line therapy is now being increasingly supplemented with immune checkpoint inhibitors; their benefit is most notable in patients whose tumors express PD-L1,[A17] but patients whose tumors demonstrate microsatellite instability or are positive for Epstein–Barr virus may also be especially sensitive to PD-1 therapy.

Some gastric cancers have overexpression of the human epidermal growth factor receptor 2 (HER2, also called ERBB2). In patients with advanced gastric or gastroesophageal junction cancers showing overexpression of HER2, the addition of trastuzumab (a humanized monoclonal anti-HER2 antibody) to chemotherapy increases survival from 11.1 months to 13.8 months. The addition of the immune checkpoint inhibitor pembrolizumab is now approved in combination with trastuzumab and chemotherapy for first-line therapy in all ERBB2+ patients with metastatic disease.

Following resistance to first-line therapy, trastuzumab deruxtecan (which is an antibody-drug conjugate consisting of trastuzumab, a cleavable tetra-peptide-based linker, and a cytotoxic topoisomerase I inhibitor) can increase median survival by about 4 months and is now approved for second-line usage.[A18] The combination of ramucirumab (a VEGF receptor antagonist) plus paclitaxel can modestly increase median survival when compared with supportive care.

Empiric third-line chemotherapy in medically fit patients can include regimens utilized in other gastrointestinal cancers, such as irinotecan/5-fluorouracil. Radiation therapy alone is ineffective and is generally used only for palliative purposes in the setting of bleeding, obstruction, or pain.

Other Management

Critical in the management of the patient with gastric cancer is meticulous attention to nutrition (jejunal enteral feedings or total parenteral nutrition), correction of metabolic abnormalities that arise from vomiting or diarrhea, and treatment of infection from aspiration or spontaneous bacterial peritonitis. Patients with early gastric cancer who receive *H. pylori* eradication treatment have a reduced risk for metachronous gastric carcinoma.[A19] To maintain lumen patency, endoscopic laser treatment or prosthesis placement can be used in a palliative fashion.

TABLE 178-3 COMMON CHEMOTHERAPY REGIMENS FOR GASTRIC CANCER

NEOADJUVANT/PERIOPERATIVE THERAPY
For Medically Fit Patients: FLOT (5-fluorouracil, leucovorin, oxaliplatin, docetaxel) given as 4 preoperative and 4 postoperative 2-week cycles
METASTATIC CANCER FIRST LINE
5-fluorouracil and platinum chemotherapy backbone with immune checkpoint inhibitor (PD-1) for PD-L1+ (or can be used more broadly in PD-L1-); for ERBB2/HER2+ patients, add trastuzumab and pembrolizumab and consider addition of an anti-EGFR antibody

PREVENTION

In patients who have a family history of gastric cancer in a first-degree relative and who are infected with *H. pylori, H. pylori* eradication therapy reduces the risk of gastric cancer by about 75%.[A20] Such treatment also has reduced the incidence of gastric cancer by 40 to 50% in high-risk patients in Southern China[A21] and in patients who have precancerous lesions.[A22] Whether such treatment is equally effective in lower-risk populations is not known.[19]

PROGNOSIS

In aggregate, the overall 5-year survival rate of patients with gastric cancer is less than 10%. Approximately one third of patients who undergo a curative resection are alive after 5 years. In patients with early gastric cancer that is confined to the mucosa and submucosa, surgical resection can be curative and improves the 5-year survival rate to more than 50%.

Prognostic factors include anatomic location and nodal status. Distal gastric cancers without lymph node involvement have a better prognosis than proximal gastric cancers with or without lymph node involvement. Other prognostic factors include depth of penetration and tumor cell DNA aneuploidy. Linitis plastica and infiltrating lesions have a much worse prognosis than polypoid disease or exophytic masses.

LYMPHOMA OF THE STOMACH

EPIDEMIOLOGY

Gastric lymphoma represents about 5% of all malignant gastric tumors and is increasing in incidence. Most gastric lymphomas are non-Hodgkin lymphomas (Chapter 171), and the stomach is the most common extranodal site for non-Hodgkin lymphomas. Patients with gastric lymphoma are generally younger than patients with gastric adenocarcinoma, but the male predominance remains.

CLINICAL MANIFESTATIONS

Patients commonly present with symptoms and signs similar to those of gastric adenocarcinoma. Lymphoma in the stomach can be a primary tumor, or it can be secondary to disseminated lymphoma.

B-cell lymphomas (Chapter 171) of the stomach are most commonly large cell with a high-grade type. Low-grade variants in the setting of chronic gastritis and are termed mucosa-associated lymphoid tissue (MALT) lymphomas. MALT lesions are strongly associated with *H. pylori* infection.

DIAGNOSIS

Radiographically, primary gastric lymphomas usually arise as ulcers or exophytic masses; diffusely infiltrating lymphoma is more suggestive of secondary lymphoma. As a result, upper gastrointestinal contrast imaging usually shows multiple nodules and ulcers for a primary gastric lymphoma and typically has the appearance of linitis plastica (see earlier) with secondary lymphoma. As with gastric adenocarcinoma, however, upper endoscopy with biopsy and cytologic examination are required for diagnosis and have an accuracy of nearly 90%. Apart from conventional histopathologic analysis, immunoperoxidase staining for lymphocyte markers is helpful in diagnosis. As with gastric adenocarcinoma, proper staging of gastric lymphoma involves endoscopic ultrasound, chest and abdominal/pelvic CT scans, and bone marrow biopsy as needed.

TREATMENT

Treatment of gastric diffuse large B-cell lymphoma is best pursued with combination chemotherapy with or without radiation therapy (Chapter 171). For MALT lesions, eradication of *H. pylori* infection with antibiotics should be attempted[20] (Chapter 125), but patients with refractory lesions that are confined to the stomach can sometimes be cured with chemoradiotherapy (Chapter 171).

OTHER MALIGNANT TUMORS OF THE STOMACH

Leiomyosarcoma (Chapter 187), which constitutes approximately 1% of all gastric cancers, usually occurs as an intramural mass with central ulceration. Symptoms may include bleeding accompanied by a palpable mass. Leiomyosarcomas are often relatively indolent; surgical resection yields a 5-year survival rate of about 50%. Metastasis can occur to lymph nodes and the liver. Other gastric sarcomas include liposarcomas, fibrosarcomas, myosarcomas, and neurogenic sarcomas.

Most gastrointestinal stromal tumors (GISTs; Chapter 187) have been associated with activating mutations in the C-*kit* gene; a subset of such tumors is associated with mutations in the platelet-derived growth factor receptor (*PDGFR*) gene.[21] C-*kit* mutations are also found in chronic and acute myelogenous leukemia (Chapters 168 and 170), and approximately 50% of GISTs respond to imatinib mesylate (400 mg daily or 400 mg twice daily for *KIT* exon 9 mutant; Chapter 170), which is typically continued for at least 3 years.[A23] If imatinib is not successful, sunitinib increases survival. If both fail, regorafenib[A24] or ripretinib[A25] under expert supervision can prolong survival.[22] Pimitespib,

which is a heat shock protein 90 inhibitor, may be useful when tyrosine kinase inhibitors are no longer successful.[A26] Carcinoid tumors (Chapter 213) may begin in the stomach and are curable by removal if they have not yet spread to the liver.

Other primary tumors can spread to the stomach. In addition to lymphomas, primary lung (Chapter 177) and breast (Chapter 183) cancers as well as malignant melanoma (Chapter 188) can metastasize to the stomach.

LEIOMYOMAS AND BENIGN TUMORS

Leiomyomas (Chapter 187), which are smooth muscle tumors of benign origin, occur with equal frequency in men and women and are typically located in the middle and distal stomach. Leiomyomas can grow into the lumen, with secondary ulceration and consequent bleeding. Alternatively, they can expand to the serosa with extrinsic compression. Endoscopy may reveal a mass that has overlying mucosa or mucosa replaced by ulceration. On upper gastrointestinal imaging, leiomyomas are usually smooth with an intramural filling defect, with or without central ulceration. However, benign leiomyomas can be difficult to distinguish from their malignant counterparts radiographically or endoscopically, so tissue diagnosis is imperative. Symptomatic leiomyomas should be removed, but those without associated symptoms do not require therapy.

Other benign gastric tumors include lipomas, neurofibromas, lymphangiomas, ganglioneuromas, and hamartomas, the last associated with Peutz-Jeghers syndrome (Chapter 179) or juvenile polyposis (when restricted to the stomach).

ADENOMAS

Gastric adenomas and hyperplastic polyps are unusual but may be found in middle-aged and elderly patients. Polyps may be sessile or pedunculated. Although isolated gastric adenomatous polyps are generally asymptomatic, some patients may have dyspepsia, nausea, or bleeding. Gastric adenomas and hyperplastic polyps are smooth and regular on upper gastrointestinal series, but the diagnosis must be confirmed by upper endoscopy with biopsy. Pedunculated polyps that are larger than 2 cm or that have associated symptoms should be removed by endoscopic snare cautery polypectomy, whereas large sessile gastric adenomatous polyps may require segmental surgical resection. If polyps progress to an intermediary stage of severe dysplasia or culminate in cancer, treatment is the same as for gastric adenocarcinoma.

179 NEOPLASMS OF THE SMALL AND LARGE INTESTINE

EDWARD CHU

NEOPLASMS OF THE SMALL INTESTINE

EPIDEMIOLOGY

Small bowel malignancies are relatively rare and account for only approximately 3% of all cancers involving the gastrointestinal (GI) tract and less than 0.5% of all cancers in the United States. In 2022, an estimated 11,790 new cases of small bowel cancers will be diagnosed, and this disease accounts for nearly 1960 deaths annually.[1] The four major histologic subtypes, which make up over 90% of small bowel cancers, include carcinoid, adenocarcinoma, lymphoma, and gastrointestinal stromal tumors (GISTs). Over the past several decades, the incidence of small bowel tumors, and in particular carcinoid tumors, has increased significantly, in part because of improved diagnostic techniques.

For small bowel tumors, the mean age at diagnosis is 65 years. Sarcomas and lymphomas present at a slightly younger age, in the range of ages 60 to 62 years, whereas adenocarcinomas and carcinoid tumors present at a mean age of 68 years. These cancers are slightly more common in men compared with women and in Blacks compared with Whites.

PATHOBIOLOGY

Adenocarcinomas typically arise from adenomas, and the adenoma-carcinoma process is driven by specific genetic alterations.[2] Large-scale genomic analysis has identified distinct genomic differences between small bowel adenocarcinomas and colorectal cancers. *HER2* point mutations, microsatellite instability, and high tumor mutational load are more common in small bowel adenocarcinomas, and potentially targetable mutations in *PIK3CA* and *MEK1* also are seen. Small bowel adenocarcinomas comprise approximately 35 to 40% of all

which is a heat shock protein 90 inhibitor, may be useful when tyrosine kinase inhibitors are no longer successful.[A26] Carcinoid tumors (Chapter 213) may begin in the stomach and are curable by removal if they have not yet spread to the liver.

Other primary tumors can spread to the stomach. In addition to lymphomas, primary lung (Chapter 177) and breast (Chapter 183) cancers as well as malignant melanoma (Chapter 188) can metastasize to the stomach.

LEIOMYOMAS AND BENIGN TUMORS

Leiomyomas (Chapter 187), which are smooth muscle tumors of benign origin, occur with equal frequency in men and women and are typically located in the middle and distal stomach. Leiomyomas can grow into the lumen, with secondary ulceration and consequent bleeding. Alternatively, they can expand to the serosa with extrinsic compression. Endoscopy may reveal a mass that has overlying mucosa or mucosa replaced by ulceration. On upper gastrointestinal imaging, leiomyomas are usually smooth with an intramural filling defect, with or without central ulceration. However, benign leiomyomas can be difficult to distinguish from their malignant counterparts radiographically or endoscopically, so tissue diagnosis is imperative. Symptomatic leiomyomas should be removed, but those without associated symptoms do not require therapy.

Other benign gastric tumors include lipomas, neurofibromas, lymphangiomas, ganglioneuromas, and hamartomas, the last associated with Peutz-Jeghers syndrome (Chapter 179) or juvenile polyposis (when restricted to the stomach).

ADENOMAS

Gastric adenomas and hyperplastic polyps are unusual but may be found in middle-aged and elderly patients. Polyps may be sessile or pedunculated. Although isolated gastric adenomatous polyps are generally asymptomatic, some patients may have dyspepsia, nausea, or bleeding. Gastric adenomas and hyperplastic polyps are smooth and regular on upper gastrointestinal series, but the diagnosis must be confirmed by upper endoscopy with biopsy. Pedunculated polyps that are larger than 2 cm or that have associated symptoms should be removed by endoscopic snare cautery polypectomy, whereas large sessile gastric adenomatous polyps may require segmental surgical resection. If polyps progress to an intermediary stage of severe dysplasia or culminate in cancer, treatment is the same as for gastric adenocarcinoma.

179 NEOPLASMS OF THE SMALL AND LARGE INTESTINE

EDWARD CHU

NEOPLASMS OF THE SMALL INTESTINE

EPIDEMIOLOGY

Small bowel malignancies are relatively rare and account for only approximately 3% of all cancers involving the gastrointestinal (GI) tract and less than 0.5% of all cancers in the United States. In 2022, an estimated 11,790 new cases of small bowel cancers will be diagnosed, and this disease accounts for nearly 1960 deaths annually.[1] The four major histologic subtypes, which make up over 90% of small bowel cancers, include carcinoid, adenocarcinoma, lymphoma, and gastrointestinal stromal tumors (GISTs). Over the past several decades, the incidence of small bowel tumors, and in particular carcinoid tumors, has increased significantly, in part because of improved diagnostic techniques.

For small bowel tumors, the mean age at diagnosis is 65 years. Sarcomas and lymphomas present at a slightly younger age, in the range of ages 60 to 62 years, whereas adenocarcinomas and carcinoid tumors present at a mean age of 68 years. These cancers are slightly more common in men compared with women and in Blacks compared with Whites.

PATHOBIOLOGY

Adenocarcinomas typically arise from adenomas, and the adenoma-carcinoma process is driven by specific genetic alterations.[2] Large-scale genomic analysis has identified distinct genomic differences between small bowel adenocarcinomas and colorectal cancers. *HER2* point mutations, microsatellite instability, and high tumor mutational load are more common in small bowel adenocarcinomas, and potentially targetable mutations in *PIK3CA* and *MEK1* also are seen. Small bowel adenocarcinomas comprise approximately 35 to 40% of all

ABSTRACT

Neoplasms of the small intestine are relatively rare and only about 3% of primary gastrointestinal (GI) cancers arise in the small intestine. The most common small bowel cancers are adenocarcinomas, carcinoids, gastrointestinal stromal tumors (GIST), and GI lymphomas. Colorectal cancer is a major public health problem in the United States and globally. It is the third most common cancer in the United States and the second leading cause of cancer mortality. This chapter focuses on the key aspects and most updated developments relating to epidemiology, pathobiology, clinical manifestations, diagnosis, treatment, and prognosis for neoplasms of both the small and large intestine.

malignant small bowel tumors, and the duodenum is the most common site of presentation in the small bowel. The majority of these adenocarcinomas are moderately or well differentiated.

Small bowel carcinoids (Chapter 213) are derived from enterochromaffin cells in the crypts of Lieberkühn, and they account for up to 40 to 45% of cancers that arise in the small bowel. Carcinoids are typically well-differentiated cancers and, in contrast to adenocarcinomas, they tend to occur in the distal ileum. Up to 30% of cases are multifocal. Other less common small bowel neuroendocrine tumors include gastrinomas and somatostatinomas (Chapter 213). Small cell cancers occur rarely in the small bowel.

About 15% of small bowel cancers are malignant connective tissue tumors. GISTs, which are derived from the interstitial cells of Cajal, account for approximately 85% of the connective tissue tumors in the small bowel (Fig. 179-1). GISTs most commonly present in the duodenum, and they often resemble soft tissue sarcomas morphologically (Fig. 179-2). However, in contrast to classic sarcomas, GISTs express the c-Kit protein (CD117). Soft tissue sarcomas, such as leiomyosarcomas, present more commonly in the stomach and rarely in the small bowel (Chapter 187).

Primary GI lymphomas represent the most common location for extranodal lymphomas, and the second most common site in the GI tract is the small intestine. The non-Hodgkin histopathologic subtype is most commonly observed, and they account for nearly 10% of all small bowel cancers. The ileum is the most common region for these extranodal GI lymphomas, presumably because this region of the small intestine is rich in submucosal lymphoid follicles. These cancers may be low- or high-grade in nature. Although they are most commonly of B-cell origin (Chapter 171), they can also arise from precursor T lymphocytes.

The small intestine is also a site for metastatic spread of advanced solid cancers. Metastatic spread can occur via direct invasion, hematogenous spread, or extension of peritoneal metastases. For example, the small bowel is the most common GI site for metastatic malignant melanoma (Chapter 188). Ovarian (Chapter 184), breast (Chapter 183), lung (Chapter 177), and other GI cancers (Chapter 178) can also spread to the small bowel.

Benign tumors originating in the small bowel include adenomas, lipomas, and leiomyomas. Desmoids, hamartomas, and hemangiomas are other benign tumors but are relatively rare. These benign tumors usually present in the distal small bowel.

Predisposing Conditions

Age is an important risk factor for small bowel cancers as it is for colorectal cancer. These cancers occur in the older age population, with a mean age of 66 years. Chronic mucosal inflammatory conditions are linked to the development of small bowel adenocarcinomas and lymphoma. Inflammatory bowel disease (Chapter 127), in particular Crohn disease, is associated with an increased risk of adenocarcinoma within the involved region of the small intestine, and the risk of small bowel adenocarcinoma increases with extent and duration of small bowel involvement. Patients with chronic immunodeficiency states and autoimmune disorders, such as celiac disease (Chapter 126), are at increased risk for developing small bowel adenocarcinomas and small bowel lymphoma.

A number of dietary factors, including red meat, salt-cured and smoked food, refined sugar, and alcohol, are associated with an increased risk of small bowel adenocarcinomas. Although tobacco exposure and obesity may increase the risk of small bowel cancers, the data on the potential role of these two factors are conflicting.

Several familial polyposis syndromes are associated with small bowel neoplasms. Familial adenomatous polyposis syndrome is associated with a 100% risk of developing colorectal cancer, and patients with this familial colorectal cancer syndrome have a 4 to 12% lifetime risk of developing cancers in the duodenum or periampullary region. The risk of cancer is related to the number of polyps and to their size, histologic type, and degree of dysplasia. Hereditary nonpolyposis colon cancer is associated with an 80% lifetime risk of colorectal cancer and a 1 to 4% lifetime risk of small bowel cancer, which represents a 100-fold increased risk when compared with the general population. Hereditary nonpolyposis colorectal cancer–associated small bowel cancers tend to present 10 to 20 years earlier than the usual age of onset for small bowel cancer. Peutz-Jeghers syndrome is associated with a 57% lifetime risk of GI cancers, with colorectal cancer the most common tumor followed by small bowel adenocarcinoma.

CLINICAL MANIFESTATIONS

Small bowel malignant tumors are usually associated with symptoms, whereas benign tumors are asymptomatic in up to 50% of patients. The most common symptom is abdominal pain. Other symptoms include weight loss, nausea and vomiting, reduced appetite, fatigue, GI bleeding, and symptoms related to GI obstruction. Duodenal primary tumors, and especially tumors in the periampullary region, can be associated with obstructive jaundice.

Small bowel carcinoid tumors are usually asymptomatic. With advanced disease and especially in the presence of hepatic metastasis, they secrete bioactive amines that can lead to symptoms typically associated with the carcinoid syndrome: flushing, wheezing, diarrhea, and right-sided heart failure (related to valvular fibrosis) (Chapter 213). Systemic symptoms are more frequent with tumors that originate in the jejunum or ileum.

Patients with lymphoma may present with evidence of lymphadenopathy, hepatomegaly, and intestinal obstruction (e.g., abdominal distention and hyperperistalsis). GI lymphomas also may present with constitutional symptoms, such as fever, night sweats, and weight loss. Benign tumors usually are incidental findings, although larger tumors may eventually cause obstruction or bleeding.

DIAGNOSIS

The diagnosis of small bowel cancer is often delayed due to its rare and nonspecific presentation. The mean duration of symptoms prior to making a definitive diagnosis of small bowel cancer ranges from 8 to 10 months. In patients with small bowel tumors, the physical examination is typically unremarkable, although some patients develop a palpable mass, distended abdomen, or ascites. Patients with a primary duodenal tumor may present with scleral icterus and jaundice resulting from biliary obstruction.

The common laboratory findings may include iron deficiency anemia (Chapter 145) or elevations in hepatic enzymes (aspartate aminotransferase [AST], alanine aminotransferase [ALT], alkaline phosphatase). The serum bilirubin level can be elevated in patients who have liver metastases or biliary obstruction. In small bowel adenocarcinoma, serum levels of the carcinoembryonic antigen (CEA) may be elevated, especially in advanced cases, but this

FIGURE 179-1. Small bowel gastrointestinal stromal tumor with ulceration.

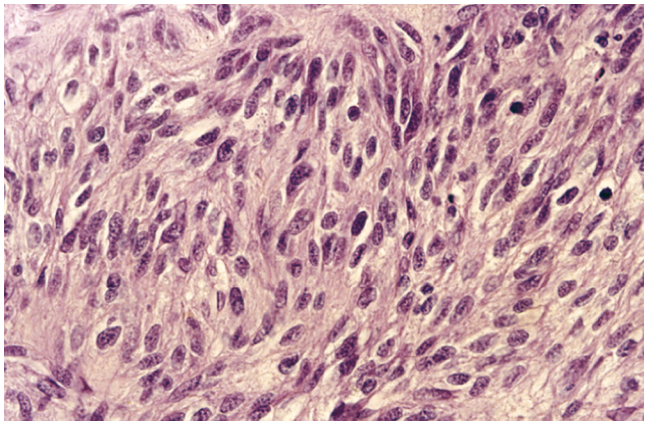

FIGURE 179-2. Histopathology of gastrointestinal stromal tumor (GIST).

marker is neither sensitive nor specific for routine diagnosis because several tumor types may present with elevated levels. In patients with neuroendocrine tumors, elevated levels of serotonin, chromogranin A, tumor-specific bioactive amines (e.g., gastrin), or urinary 5-hydroxyindoleacetic acid (5-HIAA) are commonly observed.

Imaging is required to diagnose and stage small bowel tumors, but no imaging modality is optimal.[3] Standard imaging techniques include upper GI series with small bowel follow-through, enteroclysis, transabdominal ultrasound, computed tomography (CT) scan, or magnetic resonance imaging (MRI). Enteroclysis is a double-contrast imaging study that is superior to an upper GI series with small bowel follow-through, and it has greater sensitivity to detect malignant small bowel tumors. A major limitation of enteroclysis is the inability to detect flat lesions. CT scanning of the abdomen is the most common imaging modality used in daily clinical practice, and this imaging modality is good for diagnosing primary tumors as well as metastatic disease. MRI appears to be superior to CT, especially as it relates to the detection of liver metastases as well as characterizing soft tissue sarcomas.

Carcinoids and primary neuroendocrine tumors are best imaged with nuclear medicine scans with indium-111 octreotide and/or meta-iodobenzylguanidine (MIBG). Over 90% of carcinoid tumors express somatostatin receptors, and the octreotide scan using the indium-111 tracer has high sensitivity (80 to 100%). A wide variety of small bowel cancers, including adenocarcinomas, lymphomas, and GISTs, may display uptake on positron emission tomograph (PET) scanning. However, PET is not useful for diagnosing carcinoid tumors because they are not typically FDG-avid.

Video capsule endoscopy (Chapter 120) uses a wireless endoscopic device to visualize the entire small bowel. The primary indication for video capsule endoscopy is to evaluate GI bleeding of an unknown source. In about 2 to 3% of patients who undergo capsule endoscopy for GI bleeding, a tumor is found. Capsule endoscopy can also assess the small intestine in patients who have familial adenomatous polyposis and Peutz-Jeghers syndrome, but its clinical utility as a routine screening test in such patients is unknown.

Deep enteroscopy techniques (Chapter 120) facilitate the intubation of the small bowel using long endoscopes. The small bowel may be examined antegrade (from the mouth) or retrograde (from the colon), thereby permitting direct examination of most of the small bowel. These methods are more invasive than capsule endoscopy but have the potential advantages for tissue biopsy, immediate polypectomy, and direct control of bleeding.

Staging

Staging for small bowel tumors varies by histology. Adenocarcinomas, GISTs, and neuroendocrine cancers are typically staged using specific classifications within the American Joint Committee on Cancer's (AJCC) TNM system. In contrast, non-Hodgkin lymphomas (Chapter 171) are staged in accordance with a modified Ann Arbor system originally used for the staging of Hodgkin disease (Chapter 172).

TREATMENT

Surgery

Surgical removal is the treatment of choice for localized small bowel tumors, with the extent of the surgical resection dependent on the tumor's histology and location. For adenocarcinomas in the first two portions of the duodenum, extensive pancreaticoduodenectomy is usually required, whereas small bowel carcinomas of the distal small intestine may require segmental or wide local resection of the tumor and the regional lymph nodes. En bloc resection is recommended for low-grade endocrine tumors, including regional lymph nodes. In contrast, GISTs do not require lymphadenectomy, unless the lymph nodes are grossly abnormal at the time of surgery. Surgery is not usually a primary treatment approach for lymphomas but can be considered for low-stage lymphomas. Surgery may also be required to treat complications such as bowel obstruction or perforation. Benign small bowel tumors, such as incidental lipomas, may simply be observed. Small adenomas can be removed by endoscopic polypectomy, but periampullary villous adenomas may require pancreaticoduodenectomy (Video 179-1).

Adjuvant Therapy

The role of adjuvant therapy depends on the specific type of small bowel cancer. Small bowel adenocarcinomas are generally treated similarly to colorectal cancer, with 6 months of fluoropyrimidine-based systemic chemotherapy under expert guidance for patients with lymph node involvement. Completely resected, moderately differentiated neuroendocrine cancers do not require adjuvant therapy.

For high-risk GISTs, postoperative imatinib reduces recurrence, and 3 years of treatment improves survival compared with 1 year of treatment, especially in patients with certain *Kit* exon 11 deletions as well as deletions that involve exon 11 codons 557 or 558. Emerging clinical data suggest that 5 years of adjuvant imatinib therapy may confer additional clinical benefit to patients with high-risk GISTs.[4] For other soft tissue sarcomas, adjuvant therapy has no definitive role following surgical resection. Postoperative systemic chemotherapy is recommended for both low- and high-grade lymphomas (Chapter 171).

Metastatic Disease

Metastatic small bowel carcinomas are generally treated with systemic chemotherapy regimens known to be effective against colorectal cancer, but no treatment regimen is standard.[5,6] For patients with metastatic GISTs, imatinib therapy yields median survival rates of nearly 4 years, with an estimated 10-year survival rate of about 20%.[A1] When resistance to imatinib develops, sunitinib and/or regorafenib are effective second-line treatments under expert guidance. For metastatic carcinoids that are surgically unresectable, somatostatin analogues, such as octreotide and lanreotide, are the main treatment options (Chapter 213), but agents such as 5-fluorouracil, streptozocin, and doxorubicin have been used with modest clinical activity (see Table 164-2).

PREVENTION

In patients with any of the various familial colon cancer syndromes (including familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, and Peutz-Jeghers syndrome), regular surveillance of the small intestine is required. Patients with familial adenomatous polyposis also should undergo regular screening esophagogastroduodenoscopy as part of their initial diagnostic evaluation and again at intervals of 1 to 5 years, depending on the presence and degree of duodenal polyposis. Patients with hereditary nonpolyposis colorectal cancer are also at increased risk for small bowel carcinomas, which may, in fact, be the first manifestation of their disease. Hereditary nonpolyposis colorectal cancer–associated small bowel cancer typically presents at a younger age (median, 39 years), and the duodenum is the most common site of disease (about 50% of cases). Screening should be started at age 30 years. Patients with sporadic small intestine adenomas and patients with carcinoid tumors should undergo colonoscopy given their higher risk of colonic neoplasia. Currently, no specific guidelines are available for the routine surveillance of patients with resected small bowel carcinomas.

PROGNOSIS

The overall prognosis for small bowel cancers depends on the specific pathologic subtype. For small bowel carcinomas, the 5-year survival is 50 to 85% for stage I to III patients but only 5% for stage IV. Tumor site is an important determinant of prognosis, with survival rates being worse for primary duodenal tumors compared with ileal or jejunal primary tumors. Other factors associated with poor prognosis include poor differentiation, lymph node involvement, distant metastases, and lymphovascular invasion. The tumor mutational burden and SMAD4 mutations may potentially be useful biomarkers for predicting the prognosis in small bowel cancers.[7]

Carcinoids (Chapter 213) are typically indolent, and 5-year survival rates range between 50 and 95% depending on the stage of disease. The prognosis of small intestine GISTs depends on the primary site (distal tumors have a worse prognosis), size, and mitotic activity, as well as the adequacy of surgical resection. However, 5-year survival rates approach 80% with imatinib therapy, even when complete surgical resection is not possible. For small intestinal lymphomas, the 5-year survival rate is over 60% but varies by histologic subtype.

NEOPLASMS OF THE LARGE INTESTINE

EPIDEMIOLOGY

In the United States, colorectal cancer is the third most common cancer, with an annual incidence of approximately 150,000. It is also the second-leading cause of cancer death, with approximately 53,000 deaths each year. Worldwide, an estimated 1.2 million new cases of colorectal cancer are diagnosed each year, and about 600,000 patients die from it. In the average individual, the lifetime risk of developing colorectal cancer is high, about 1 in 20.

About 75% of large bowel cancers arise in the proximal colon. Colorectal cancer is more common in the elderly, with a median age of approximately 73 years, but about 10% of cases are in patients younger than age 50 years. The overall incidence and mortality of colorectal cancer have declined significantly over the past 2 decades, especially for patients older than 50 years

of age. However, this decline has not occurred equally in all populations and varies according to age. For example, the incidence of colorectal cancer in adults younger than age 50 years has increased by more than 20% since 2000, and this rise has been driven by tumors in the distal colon and rectum.[8] The incidence in individuals between ages 20 and 49 years has also been increasing, with the largest increase, approaching 90%, in Hispanics ages 20 to 29 years.[9] The overall incidence of left-sided or distal colon cancer has decreased, likely because of effective distal large bowel screening, but the incidence of right-sided or proximal colon cancer has been steadily increasing in the United States.

Colorectal cancer is slightly more common in men than in women, and men, on average, develop the disease 5 to 10 years younger than women. The mortality associated with colorectal cancer is also 25% higher in men. Of all the ethnic groups in the United States, Blacks have the highest rates of colorectal cancer, and they are diagnosed an average of 5 to 10 years earlier than White patients, with an especially increased frequency under age 50 years. The mortality associated with this disease is 20% higher in Blacks than in Whites.

Risk Factors

Sporadic colorectal cancer accounts for 80 to 85% of cases, and the main risk factors include older age, male sex, African ancestry, family history, inflammatory bowel disease, obesity, diabetes mellitus and insulin resistance, tobacco use, and alcohol use. The consumption of red meat or processed foods and reduced intake of fiber, green leafy vegetables, and fruits also contributes to the risk of colorectal cancer. The presence of certain intestinal microbiota, including bacteria (*Streptococcus bovis*, *Fusobacterium*, and various *E. coli* strains) and viruses (human papillomavirus), may be risk factors. Factors associated with a reduced risk of colorectal cancer include greater physical activity and exercise; higher dietary intake of fiber, fruit, and vegetables; regular use of aspirin and nonsteroidal anti-inflammatory agents; and supplementation with folic acid, calcium, and vitamin D.

Age is the strongest risk factor for sporadic colorectal cancer, with risk increasing substantially starting at age 50 years. Nevertheless, 10 to 12% of colorectal cancers are diagnosed before age 50 years.[10] Family history is important, even in the absence of defined familial colon cancer syndromes. If a first-degree relative has colorectal cancer, a person's risk for developing colorectal cancer is two- to three-fold higher, with the risk rising to five- to six-fold when two first-degree relatives have colorectal cancer. Even if a first-degree relative has an adenoma, the risk of colorectal cancer is increased two-fold. Patients with a history of ulcerative colitis or Crohn disease (Chapter 127) have a 60% higher risk of colorectal cancer[11] compared with the general population, and the risk is related to the extent and duration of large bowel involvement.

PATHOBIOLOGY

Adenocarcinomas comprise more than 90% of colorectal cancers. Other relatively rare histologic subtypes include neuroendocrine cancers, epidermoid carcinomas, hamartomas, lymphomas, and sarcomas (including GISTs). Composite tumors are also observed, most commonly adenocarcinomas with neuroendocrine features.

Adenocarcinomas

Colorectal adenocarcinomas arise from the columnar glandular epithelium of the mucosa. Mucinous cancers make up the large majority of colorectal cancer, whereas only about 20% do not produce mucin. Mucinous cancers tend to develop in the right side of the colon. The medullary carcinoma subtype is characterized by large, eosinophilic cells and has a heavy infiltration of tumor-infiltrating lymphocytes. These tumors exhibit a high degree of microsatellite instability because they are deficient in one or more of the mismatch repair proteins. Medullary carcinomas arise more commonly on the right side of the colon, are seen in older women, and are less likely to spread to lymph nodes. Signet ring cancer is characterized by large numbers of single tumor cells with nuclear displacement by intracytoplasmic mucin.

Carcinogenesis for colorectal adenocarcinomas is caused by a multistep process when multiple genetic alterations occur over time (Fig. 179-3) in one or more of three pathways: chromosomal instability, microsatellite instability, and CpG island methylator phenotype. The chromosomal instability pathway, which accounts for up to 70% of cases of sporadic colorectal cancer, is most commonly related to mutations in the *APC* (tumor suppressor gene) and in the *KRAS* gene (proto-oncogene that regulates transduction of mitogenic signals across cell membranes). In familial adenomatous polyposis, germline mutations in *APC* are the result of chromosomal instability that leads to aneuploidy (imbalance in chromosome number), genomic amplifications, and loss of heterozygosity (cells have only one gene allele because of the loss of individual chromosomes during mitosis). Several other gene mutations lead to colorectal cancer, including the colon cancer (*MCC*) gene (a tumor suppressor gene), p53 (a key regulator of the cell cycle), *VEGF*, *MYC*, *MET*, *LYN*, and *PTEN*. Many of the mutational events have downstream effects on the Wnt signaling pathway.

The microsatellite instability pathway is a result of defects in DNA mismatch repair. Microsatellites are short repeating nucleotide sequences that are prone to errors because of their repetitive nature. Microsatellite instability–high tumors are caused by defects in the function of mismatch repair genes, especially *MLH1*, *MSH2*, *MSH6*, and *PMS2*. Germline mutations in these genes cause HNPCC (Lynch syndrome), but silencing of *MLH1* by hypermethylation is the most common molecular mechanism underlying mismatch repair defects in sporadic colorectal cancer. Microsatellite instability–high tumors are more

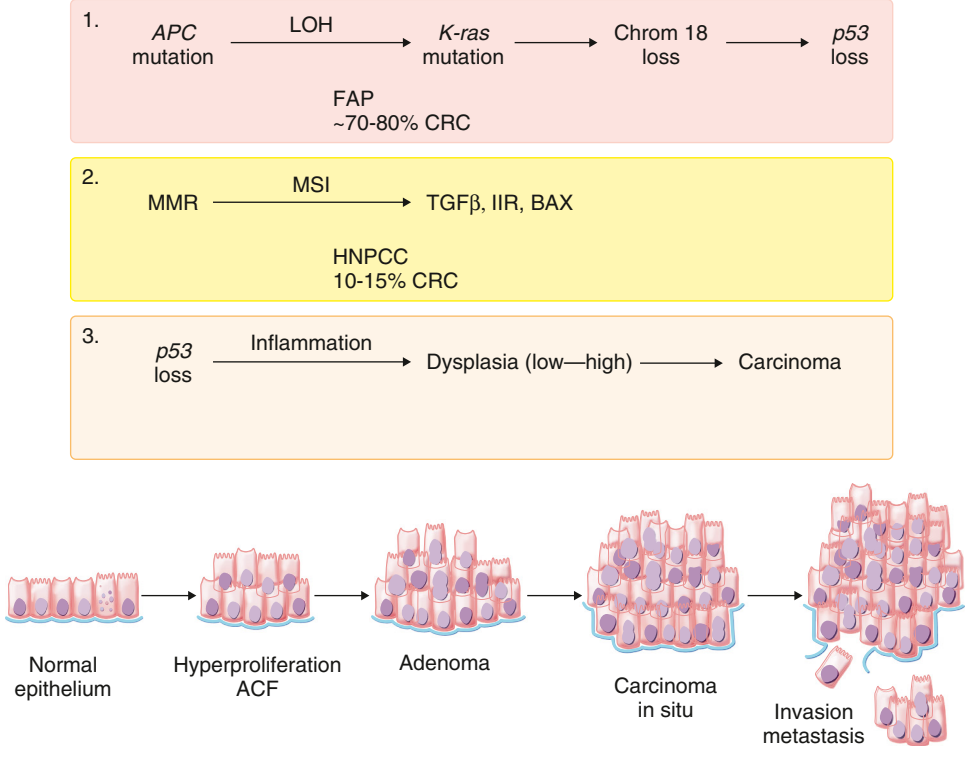

FIGURE 179-3. The molecular basis of colorectal cancer. Sequence-specific genetic alterations result in the transition from normal large bowel epithelium to invasive cancer. *Panel 1* demonstrates chromosomal instability, *Panel 2* illustrates microsatellite instability, and *Panel 3* shows the CpG island methylator phenotype. ACF = aberrant crypt foci; *APC* = adenomatous polyposis coli; BAX = apoptosis-related proteins; CRC = colorectal cancer; FAP = familial adenomatous polyposis; HNPCC = hereditary nonpolyposis colorectal cancer; IIR = type II receptor; LOH = loss of heterozygosity; MMR = mutation mismatch repair; MSI = microsatellite instability; TGF-β = transforming growth factor-β.

common in women and in the right colon, and they are often poorly differentiated and associated with a lymphocytic infiltration.

In the CpG island methylator phenotype pathway, hypermethylation of DNA promoter regions silences tumor suppressor genes, thereby leading to carcinogenesis. In colorectal cancer, hypermethylated genes include *APC*, *MCC*, *MLH1*, and *MGMT*. CpG island methylator phenotype-high tumors often have *BRAF* mutations, are poorly differentiated, have mucinous or signet ring morphology, and are microsatellite instability high. The precursor is likely to be a sessile serrated adenoma.

Neuroendocrine Cancers

Neuroendocrine cancers include carcinoid tumors (Chapter 213) and small cell carcinomas. Carcinoid tumors are the second most common colorectal neoplasms after adenocarcinomas, and are more common in non-Whites. In the distal bowel, carcinoids rarely are hormonally inactive.

Epidermoid Carcinomas

Epidermoid carcinomas are usually of the squamous cell subtype. They tend to be more common in women and Hispanic patients. More than 90% of epidermoid carcinomas are located in the rectum, and they tend to be moderately or poorly differentiated.

Lymphomas

Primary large intestinal lymphomas (Chapter 171) make up about 10 to 20% of all GI lymphomas but less than 1% of all colorectal cancers. The cecum is the most common site, and they are more common in males and in the elderly. The large majority of these large bowel lymphomas are of B-cell origin.

Sarcomas

Large bowel sarcomas are relatively rare, and a majority are leiomyosarcomas (Chapter 187). These tumors commonly present in the rectum, where they are usually localized at the time of diagnosis, regardless of their grade. GISTs and Kaposi sarcomas (Chapter 359) occur in the large bowel.

POLYPS OF THE COLON

A polyp is a grossly visible epithelial-cell mass that protrudes out from the intestinal mucosal surface into its lumen. A polyp may be flat, sessile, or pedunculated (attached by a stalk). Polyps can be non-neoplastic or neoplastic (adenomatous). Polyps usually are asymptomatic but can occasionally cause bleeding, prolapse, or obstruction. Non-neoplastic polyps are not premalignant, but neoplastic polyps can become a true cancer.

FAMILIAL COLORECTAL CANCER SYNDROMES

Several well-defined familial syndromes are associated with an increased risk for colorectal cancer. These syndromes include hereditary nonpolyposis colorectal cancer (HNPCC), Muir-Tore syndrome, familial adenomatous polyposis, Gardner syndrome, Turcot syndrome, *MUTYH*-associated polyposis, Peutz-Jeghers syndrome, and juvenile polyposis (Table 179-1).

Hereditary Nonpolyposis Colorectal Cancer

Hereditary nonpolyposis colorectal cancer (HNPCC), also known as Lynch syndrome, is the most common hereditary colorectal cancer syndrome and accounts for approximately 2% of all cases of colorectal cancers. The cause is a highly penetrant, autosomal dominant, loss-of-function germline mutation in genes (*MLH1, MSH2, MSH6*, and *PMS2*) that repair DNA base pair mismatches occurring during DNA replication.[12]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Although patients may have several adenomas, the diffuse polyposis characteristic of familial adenomatous polyposis is not typically observed. Synchronous and metachronous tumors are common. Colon cancers associated with HNPCC have a right-sided predominance (before the splenic flexure). These cancers are often poorly differentiated but generally have a better prognosis than typical sporadic colorectal cancers. Patients with HNPCC also have a higher risk for other solid tumors, especially endometrial cancer, as well as cancers of the ovary (Chapter 184), stomach (Chapter 178), small bowel, pancreas (Chapter 180), hepatobiliary tract (Chapter 181), and ureter (Chapter 182).

The median age for diagnosis of HNPCC is the mid-40s, which is 25 to 30 years younger than the age of presentation for sporadic colorectal cancer. Testing of patients for HNPCC includes testing the tumor for microsatellite instability and staining for the protein products of mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, and *PSM2*).[13] A positive screen does not definitively diagnose HNPCC, because up to 15% of sporadic colorectal cancers may have these features. Germline testing of peripheral blood is generally preferred, but saliva or a buccal swab also can be tested to confirm the presence of mutations in one of the mismatch repair genes and to make the definitive diagnosis of HNPCC.

The Amsterdam criteria define HNPCC: (1) an HNPCC-associated cancer (colorectal cancer or cancers of the stomach, small bowel, renal pelvis, ureter, or endometrium) has been diagnosed in three or more relatives, one of whom is a first-degree relative of the other two, in the absence of familial adenomatous polyposis; (2) colorectal cancer has developed in at least two successive generations; and (3) one or more family members was diagnosed before age 50 years, with one being a first-degree relative of the other two. The revised Bethesda criteria define HNPCC when: (1) colorectal cancer is diagnosed in a patient younger than 50 years of age; (2) synchronous or metachronous colorectal cancer or other Lynch syndrome–associated tumors are diagnosed, regardless of age; (3) colorectal cancer has a high degree of microsatellite instability in a patient younger than 60 years of age; (4) colorectal cancer is diagnosed in one or more first-degree relatives with a Lynch syndrome cancer, with one of the cancers diagnosed at younger than 50 years of age; (5) colorectal cancer is diagnosed in two or more first-degree or second-degree relatives with a Lynch syndrome cancer, regardless of age.

Muir-Torre Syndrome

The Muir-Torre syndrome is a rare autosomal dominant syndrome that is an HNPCC subtype. Muir-Torre syndrome also arises from mutations in DNA mismatch repair genes (*hMLH1, hMSH2*, and *MSH6*), and patients present with colorectal cancer, genitourinary tract cancers, and skin lesions, including keratoacanthomas and sebaceous tumors.

TABLE 179-1 GENERAL FEATURES OF INHERITED COLORECTAL CANCER SYNDROMES

SYNDROME	POLYP HISTOLOGY	POLYP DISTRIBUTION	AGE OF ONSET	RISK OF COLON CANCER	GENETIC LESION	CLINICAL MANIFESTATIONS	ASSOCIATED LESIONS
Familial adenomatous polyposis	Adenoma	Large intestine, duodenum	16 yr (range, 8-34 yr)	100%	5q (*APC* gene)	Rectal bleeding, abdominal pain, bowel obstruction	Desmoids, CHRPE
Peutz-Jeghers syndrome	Hamartoma	Large and small intestine	First decade	Slightly above average	19p (*STK11*)	Possible rectal bleeding, abdominal pain, intussusception	Orocutaneous melanin pigment spots, other tumors
MUTYH-associated polyposis	Adenoma	Large intestine, duodenum	45-50 yr (range, 13-60 yr)	75% (range, 50-100%)	1p (*MUTYH* gene)	Rectal bleeding, abdominal pain, bowel obstruction	CHRPE, osteomas
Juvenile polyposis	Hamartoma (rarely adenoma)	Large and small intestine	First decade	≈9%	*PTEN*, *SMAD4*, *BMPR1*	Possible rectal bleeding, abdominal pain, intussusception	Pulmonary AVMs
Hereditary nonpolyposis colon cancer	Adenoma	Large intestine	40 yr (range, 18-65 yr)	30%	Mismatch repair genes*	Rectal bleeding, abdominal pain, bowel obstruction	Other tumors (e.g., ovary, uterus, pancreas, stomach)

*Including hMSH2, hMSH3, hMSH6, hMLH1, hPMS1, and hPMS2.
AVM = arteriovenous malformation; CHRPE = congenital hypertrophy of the retinal pigment epithelium.

Familial Adenomatous Polyposis

Familial adenomatous polyposis is an autosomal dominant condition with incomplete penetrance and is the result of a mutation in the adenomatous polyposis coli *(APC)* gene.[14] Patients have hundreds to thousands of adenomatous polyps (Fig. 179-4) that occur relatively evenly throughout the colon and that usually appear by early in the second decade of life. GI symptoms usually develop in the third or fourth decade, and nearly every untreated patient develops colorectal cancer by age 40 years. Small bowel adenomas, usually in the duodenum, are seen in 45 to 90% of cases, and periampullary duodenal cancer develops in about 10% of patients. Patients with an attenuated form of familial adenomatous polyposis have fewer than 100 colonic adenomas with a right colon predominance and develop colorectal cancer about 10 years later.

Gardner Syndrome

Gardner syndrome is a subtype of familial adenomatous polyposis and is also the result of mutations in the *APC* gene. It is characterized by extra-intestinal clinical features, including soft tissue tumors (e.g., lipomas, sebaceous cysts, and fibrosarcomas), supernumerary teeth, desmoid tumors, osteomas (particularly mandibular), mesenteric fibromatosis, and congenital hypertrophy of the retinal pigment epithelium. Gardner syndrome and familial adenomatous polyposis differ because of variations in the location of the *APC* mutation, modifying genes, and environmental factors. However, the adenomatous polyps in Gardner syndrome and in familial adenomatous polyposis have similar malignant potential, so screening and treatment recommendations also are similar.

Turcot Syndrome

Turcot syndrome is the combination of colorectal polyposis, colorectal cancer, and central nervous system malignancy. *APC* gene mutations cause two-thirds of cases, whereas the other one-third result from the same DNA mismatch repair gene mutations that are seen in HNPCC. The central nervous system malignancies include medulloblastomas, glioblastomas, and ependymomas.

MUTYH-Associated Polyposis

MUTYH-associated polyposis is an autosomal recessive syndrome caused by mutations in the *MUTYH* gene (also called MYH [mutY homologue]). Underlying defects in base excision repair as well as acquired mutations in the *APC* gene and other genes (e.g., *KRAS*) lead to colonic polyposis and an increased risk of developing colorectal cancer. About 0.4 to 0.7% of patients who develop colorectal cancer have a homozygous *MUTYH* mutation. The phenotype is similar to attenuated familial adenomatous polyposis. Patients have up to hundreds of adenomas throughout the colon and may also have multiple hyperplastic polyps as well as serrated adenomas. Compared with familial adenomatous polyposis, the colorectal cancers of *MUTYH*-associated polyposis are more likely to be right-sided, with an average age of onset at 45 to 50 years. Extra-colonic features include gastroduodenal polyps, duodenal carcinoma, breast cancer, ovarian cancer, bladder cancer, skin cancer, osteomas, and congenital hypertrophy of the retinal pigment epithelium.

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome is a rare but highly penetrant autosomal dominant syndrome caused by a mutation in the serine-threonine kinase *(STK11)* gene located on chromosome 19p. Nearly all patients have characteristic melanin spots on their lips, buccal mucosa, and skin. The average age at diagnosis is the third decade. The syndrome is characterized by benign hamartomatous polyps predominantly in the small intestine, stomach, and colon, occasionally accompanied by adenomatous and hyperplastic polyps. The most common symptoms are small bowel intussusception, obstruction, and GI bleeding. Nearly 50% of patients develop a malignancy by age 65 years, most commonly in the small intestine, stomach, colon, pancreas, testes, breast, ovary, cervix, or uterus. Because genetic testing is not widely available, first-degree relatives should be screened annually from birth, looking especially for melanotic spots, precocious puberty, and testicular tumors.

FIGURE 179-4. Resected colon of a patient with familial adenomatous polyposis.

Juvenile Polyposis

Familial juvenile (non-neoplastic, hamartomatous) polyposis is a rare (<1 in 100,000 births) syndrome in which patients develop 10 or more hamartomatous, non-neoplastic polyps (histologically distinct from those seen in Peutz-Jeghers syndrome) throughout their GI tract. This syndrome results from a highly penetrant autosomal dominant mutation in the *SMAD4*, *PTEN*, or *BMPR1A* gene. Symptoms and signs include abdominal pain, rectal bleeding, intestinal obstruction, and anemia by early adolescence. Pulmonary arteriovenous malformations are also seen. The risk of malignancy can be as high as 20%, with a median age of 37 years.[15]

NON-NEOPLASTIC POLYPS

About 50% of all large bowel polyps in average-risk individuals older than age 50 years are non-neoplastic (nonadenomatous) polyps. Nonadenomatous polyps can be hyperplastic, inflammatory, lymphoid, or juvenile. Hyperplastic polyps usually are caused by abnormal maturation of the mucosal epithelial cells. Hyperplastic polyps usually are small and seen mostly in the distal sigmoid colon and rectum. Hyperplastic polyps are not premalignant.

Patients with inflammatory bowel disease (Chapter 127) often have inflammatory pseudopolyps that are distinguished from neoplastic polyps only by biopsy. Lymphoid polyps contain exaggerated intramucosal lymphoid tissue. Juvenile polyps are focal hamartomatous malformations that are caused by abnormal development of the lamina propria and that are usually seen in the rectum of young children.

SERRATED POLYPS

Sessile serrated adenomas are neoplastic lesions with a right colon predominance and a high malignant potential.[16] Serrated polyps present with a disorganized and distorted crypt growth pattern. Because they are sessile or flat, they can be difficult to visualize on endoscopy. Their pathogenesis is via hypermethylation of CpG islands ("CIMP-high") and the *MLH1* mismatch repair gene, in the presence of *BRAF* mutations. As a result, serrated polyps exhibit a high degree of microsatellite instability.

Traditional serrated adenomas are rare and histologically distinct from sessile serrated adenomas. They commonly exhibit high-grade dysplasia and oftentimes carcinoma in situ.

ADENOMATOUS POLYPS

Adenomatous chronic polyps (adenomas) are benign glandular tumors with malignant potential. On pathologic examination, they can have evidence for low- or high-grade dysplasia. Adenomatous polyps have an anatomic distribution similar to colorectal adenocarcinoma, can vary in size, and may be sessile, flat, or pedunculated. Adenomatous polyps are the precursor lesions for colorectal adenocarcinoma. Furthermore, screening, early detection, and removal of adenomatous polyps substantially reduce the risk of subsequent colorectal cancer.

EPIDEMIOLOGY

Adenomatous polyps are relatively common and become more common with age: more than 15% of healthy women and more than 25% of healthy men over age 50 years have adenomas. The prevalence of adenomas tends to be higher in Western countries and wherever colorectal cancer is more common. In addition to defined genetic risks seen in familial colorectal cancer syndromes, sporadic adenomas have a familial component. For example, if a first-degree relative has an adenomatous polyp, an individual's risk is increased. In the United States, Blacks have a higher risk relative to Whites of European descent, whose risks, in turn, are similar to those of Asian and Hispanic individuals.

PATHOBIOLOGY

The epithelial cells in the large bowel undergo continuous self-renewal, with complete turnover every 3 to 8 days. Adenomatous polyps are caused by the sequence-specific acquisition of mutations that favor cell proliferation over cell death. Undifferentiated cells accumulate at the luminal surface, continue to divide, and eventually form an adenomatous tissue mass.

Adenomas can be tubular, villous, or tubulovillous. Most adenomas (70 to 85%) removed at colonoscopy are tubular; they typically are small, pedunculated, and composed of dysplastic glands that divide and branch out from the mucosal surface. Tubular adenomas rarely have high-grade dysplasia or carcinoma in situ. By comparison, villous adenomas (<5% of all adenomas) are usually large, sessile, and composed of dysplastic epithelium that projects into the intestinal lumen. Villous adenomas often have high-grade dysplasia or even carcinoma in situ. Tubulovillous adenomas (10 to 25% of all adenomas) include both tubular and villous components. An adenoma is considered "advanced" if it is at least 1 cm in size or has villous histology or high-grade dysplasia. Patients with advanced adenomas or three or more adenomas have a much higher risk of developing synchronous or metachronous colorectal cancer. In a patient who has a first documented adenoma, the risk of an additional adenoma is 30 to 50%.

CLINICAL MANIFESTATIONS

Most adenomatous polyps are asymptomatic and discovered only at the time of colorectal screening. Some patients, however, may present with an asymptomatic positive stool occult blood test or overt evidence of a lower GI bleed. Less than 5% of all adenomas will eventually develop into carcinomas: 1 to 3% of polyps smaller than 1 cm, 10% of polyps between 1 and 2 cm, and 40% of polyps larger than 2 cm. All adenomas contain some level of dysplasia, and higher-grade dysplasia carries a 30% risk of undergoing malignant transformation.

DIAGNOSIS

Colonic and rectal polyps and cancer can be diagnosed by several methods, including endoscopy, barium radiography, or CT colography (virtual colonoscopy). Colonoscopy is the preferred method because of its high accuracy and ability to perform a biopsy of and remove most polyps immediately. Nevertheless, colonoscopy may miss 6 to 12% of large (≥1 cm) polyps and 5% of cancers. By comparison, barium enemas miss about 50% of polyps that are larger than 1 cm. CT colography is sensitive for detecting large (>1 cm) polyps (>85%) and for detecting cancers (96%) but much less sensitive and specific for polyps smaller than 1 cm. Although CT colography is noninvasive and relatively quick, it still requires bowel preparation and exposes the patient to ionizing radiation. Nonpolypoid (flat and depressed) colorectal neoplasms, which are more likely to be carcinomatous than are polypoid lesions, are found on colonoscopy in almost 10% of asymptomatic and symptomatic adults but are much less likely to be diagnosed by barium radiography or CT colography.

Flexible sigmoidoscopy can be used to screen average risk asymptomatic individuals, but it detects only 50 to 60% of all polyps and cancers. Patients with polyps detected by barium radiography, CT colography, or flexible sigmoidoscopy should undergo colonoscopy to remove the lesion and to search for additional polyps or mass lesions. This need for subsequent colonoscopy underscores the attractiveness of using it as the initial screening modality.

TREATMENT

Neoplastic polyps should be removed endoscopically to reduce the risk of subsequent colorectal cancer. A pedunculated adenoma usually can be removed intact by snare polypectomy (Video 179-2), whereas sessile polyps may require piecemeal snare resection. Pathologic evaluation should assess the presence or absence of cancer; if malignant tissue is identified, it should be evaluated for its histologic grade, vascular and lymphatic spread, and adenoma-free margin. Unfavorable histopathologic factors that require prompt surgical resection after endoscopic polypectomy include poorly differentiated histology, vascular invasion, lymphatic invasion, and incomplete resection. Malignant pedunculated polyps can be treated with endoscopic resection alone if the cancer is confined to the submucosa and no unfavorable histologic features are present. When a malignant sessile polyp is removed endoscopically, the potential risk of recurrence or lymph node involvement must be weighed against the risks of definitive surgery in each individual patient.

PROGNOSIS

Patients who have undergone endoscopic removal of a previously diagnosed adenomatous or sessile serrated polyp are at increased risk for the subsequent development of adenomas and colorectal cancer. The recommended surveillance post-resection depends on the primary lesions, size, and histology, as well as the number of adenomas (Table 179-2).[17] If a low-risk patient has just 1 or 2 small tubular adenomas, surveillance colonoscopy can be delayed for 5 to 10 years. By comparison, patients who have multiple (>2) adenomas, large (≥1 cm) adenomas, adenomas with villous or high-grade histology, or numerous (>10) adenomas, should undergo repeat colonoscopy within 3 years. After removal of a large (≥2 cm) adenoma or the piecemeal resection of any adenoma, colonoscopy should be repeated within 6 months to determine whether the original resection was complete. For sessile serrated polyps smaller than 10 mm without dysplasia, surveillance colonoscopy is recommended at 5 years, but the recommended interval is 3 years if the serrated polyp showed high-grade dysplasia or was a traditional serrated adenoma (Video 179-3).

ADENOCARCINOMA OF THE COLON AND RECTUM

CLINICAL MANIFESTATIONS

Patients with early-stage colon cancer are typically asymptomatic, and the cancer is usually discovered upon routine screening. Symptoms usually arise when the tumor grows into the bowel lumen or when the tumor invades adjacent anatomic structures. Common symptoms related to colorectal cancer include lower abdominal pain, change in bowel function, GI bleeding (Chapter 121), anemia, and alterations in stool caliber. Anorexia, weight loss, and fatigue may develop, and liver metastases can be manifested by hepatomegaly, jaundice, abdominal fullness, or ascites.

Symptoms also depend on the primary site (Fig. 179-5). Proximal lesions more frequently present with iron deficiency anemia (Chapter 145) resulting from occult blood loss. For lesions that occur in the distal colon, the usual presenting symptoms include a change in bowel habits, such as constipation or diarrhea, and hematochezia. Tumors arising in the rectum usually present with changes in stool caliber, rectal bleeding, and rectal pain. In some cases when the rectal tumor involves sacral nerve plexi, significant neuropathic pain may be present.

TABLE 179-2 COLONOSCOPY SURVEILLANCE INTERVALS

MOST ADVANCED FINDING	INTERVAL
No polyps or small (<10 mm) hyperplastic polyps	10 yr
1-2 adenomas, <1 cm	5-10 yr
3-10 adenomas or adenoma with villous features, ≥1 cm, or with high-grade dysplasia	3 yr
>10 adenomas	<3 yr
Sessile adenoma ≥ 2 cm, piecemeal excision	2-6 mo
Serrated lesions:	
• <10 mm, no dysplasia	5 yr
• ≥10 mm or dysplasia	3 yr

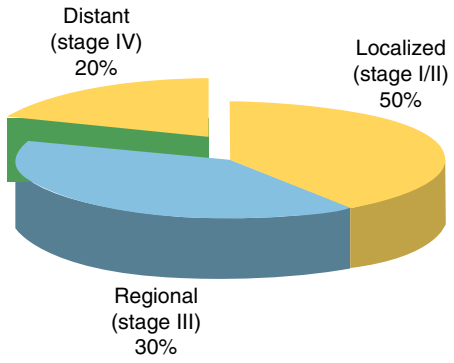

FIGURE 179-7. Stage of disease at time of initial presentation.

DIAGNOSIS

A careful history, physical examination, and radiologic evaluation are important in making the diagnosis. The patient should be questioned about a history of adenomatous polyps or colorectal cancer, a history of inflammatory bowel disease, and any family history of colorectal cancer or other solid tumors. On physical examination, extra-intestinal lesions characteristic of Peutz-Jeghers syndrome or Gardner syndrome may be noticed. Metastatic disease to the liver or lymph nodes may present with hepatosplenomegaly or lymphadenopathy, and abdominal fullness or ascites may reflect peritoneal involvement. Digital rectal examination may reveal a mass in the distal rectal region or spread of the tumor to the rectal shelf or pelvis. Examination of the stool may show frank or occult blood in up to 80% of advanced cases. Iron deficiency anemia and elevated liver enzymes (AST, ALT, and alkaline phosphatase) and serum bilirubin may aid in the diagnosis. The peripheral blood levels of the tumor markers (CEA and CA19-9) may be elevated, but these serum markers are relatively insensitive and can be elevated in other solid tumors.

The approaches for making the definitive diagnosis of colorectal cancer are similar to those used to detect adenomatous polyps. Colonoscopy is considered the standard for all patients with occult blood in their stools, unexplained iron deficiency anemia, or symptoms and signs suggestive of colorectal cancer (Fig. 179-6).

For rectal cancer, endoscopic ultrasound combines high-frequency ultrasonography with video endoscopy. This procedure is superior to CT to stage the tumor by accurately determining the degree of invasion as well as detecting and sampling any enlarged lymph nodes. Endoscopic ultrasound also is highly sensitive for detecting recurrent rectal cancer after a low anterior resection. MRI also can accurately stage rectal cancer and may be preferable to endoscopic ultrasound.

Consensus guidelines recommend CT scans of the chest, abdomen, and pelvis because advanced liver metastases or involvement of other sites often preclude immediate surgical resection of the primary tumor. PET scans can confirm systemic disease and are useful before resection of a solitary metastatic site and in patients who have a rising CEA or new symptoms suggestive of progressive disease, despite no change in their CT scans. PET scans also may be used to evaluate abnormal lesions seen on CT. However, PET has no specific role in the routine evaluation of patients with colorectal cancer. Plain chest radiographs are not sufficiently sensitive to detect the presence of metastatic lesions in the lungs, and plain abdominal films are useful only to aid in the diagnosis of bowel obstruction.

Histopathologic analysis is critical for making the diagnosis of colorectal cancer. Additional studies to evaluate immunohistochemical expression of certain key cellular proteins may be helpful in identifying adenocarcinomas of colorectal cancer origin. For example, cytokeratin 20 (CK20) and caudal-type homeobox 2 (CDX2) are two of the most sensitive and specific markers used to help diagnose colorectal cancer. Immunohistochemistry also can be helpful in making the diagnosis of defective mismatch repair by testing for the protein expression of the four main MMR genes: *MLH1, MSH2, PMS2*, and *MSH6*.

Staging

Accurate staging is critical for determining both prognosis and treatment. Colorectal cancer is staged according to the tumor, node, and metastasis (TNM) classification system based on the physical examination, radiography, endoscopy, surgery, and pathologic stage: stage I cancers penetrate into but not through the bowel wall (T1–2N0M0); stage II cancers penetrate through the bowel wall and can involve nearby organs but do not spread to regional lymph nodes; stage III cancers involve regional lymph nodes (Fig. 179-7); and stage IV disease spreads to the liver, lung, lymph nodes, and peritoneum. In the United States, about 50% of patients present with stage I or II disease, 30% with stage III disease, and 20% with advanced, metastatic disease. In general, primary tumors that arise in the colon follow an orderly spread to the regional lymph nodes, then to the liver, and then to the lungs and other distant sites. In contrast, because of the dual venous drainage of the rectum to the portal vein and inferior vena cava, primary rectal tumors may spread via hematogenous dissemination to the lungs before any liver involvement.

TREATMENT

Surgery

Surgical resection is the primary treatment for early-stage, locally confined colon cancer (stage 0 and stage I). Highly selected patients with site-limited metastatic disease (stage IV) also may undergo surgery with curative intent. Curative surgery aims to remove the primary tumor with tumor-free margins, as well as to remove the primary feeding arterial vessel and corresponding lymphatics en bloc. A minimum of 12 lymph nodes should be removed and examined microscopically for accurate staging. Synchronous colon cancers can be removed individually by subtotal colectomy. Any adjacent adherent structures should be resected en bloc. Prophylactic oophorectomy is not recommended, but if one ovary is grossly involved, the other should be removed as well given the risk of contralateral involvement. Laparoscopic resection is as safe and effective as open resection and requires a modestly shorter recovery time.[18]

For rectal cancer, the main goal of surgery is to preserve the function of the anal sphincter. For cancers involving the distal rectum, the recommendation is total mesorectal excision with en bloc removal of the lymphovascular and fatty envelope surrounding the rectum. For upper rectal tumors, by comparison, tumor-specific mesorectal excision (en bloc removal of the mesorectum 5 cm distal to the tumor) is sufficient. For minimal-risk (T1 disease, size <3 cm, well differentiated, within 8 cm of the anal verge, no lymphovascular invasion, and less than one third circumferential) low rectal cancers, local transanal excision is acceptable. Postoperatively, increased bowel frequency is common, and some patients develop fecal incontinence or evacuation dysfunction (Chapter 131). As such, the main focus in patients with rectal cancer is to preserve the function of the anal sphincter.

Obstructing tumors should be immediately resected with bowel re-anastomosis. Proximal diversion may be the only initial option for an advanced unresectable cancer, with future resection followed by ostomy closure if the primary tumor responds to the point where it can later be removed. Endoscopic stenting may sometimes relieve acute obstruction. Perforated bowel must be resected, with or without diversion, prior to re-anastomosis. In patients who present with synchronous colorectal cancer and unresectable metastases, an asymptomatic primary tumor can be treated safely with systemic medical therapy without surgery, with a low probability that serious complications will require immediate surgical intervention.

Post-Surgical Surveillance

Active surveillance is recommended after surgical resection of early-stage colon and rectal cancer because the risk for recurrent disease is highest within the first 2 to 3 years after surgery and adjuvant chemotherapy for patients with stage II or III cancer. The American Society of Clinical Oncology recommends a history and physical examination every 3 to 6 months for 5 years, annual chest and abdominal CT scans for 3 years after resection of high-risk primary tumors, and the addition of pelvic CT scanning for primary rectal cancer. However, CT plus CEA screening at 12 and 36 months appears to be as good as more frequent screening for stage II and III disease.[A2] Colonoscopy should be performed 1 year after the completion of adjuvant chemotherapy, and, if completely negative, every 5 years thereafter. Serum CEA levels should be measured every 3 to 6 months for 5 years.

Radiation Therapy

Radiation therapy is usually not considered as a treatment option for surgically resected early-stage colon cancer nor for the treatment of a primary colon cancer when metastatic disease is present. The major role for radiation therapy is in the combined modality treatment of locally advanced rectal cancer. Certain colorectal cancers are at high risk for locally recurrent disease, such as T4 tumors with penetration to a fixed structure especially within the pelvic region, may be considered for postoperative radiation therapy. However, no randomized clinical trials have documented benefit of radiation therapy in this setting. Palliative

radiation therapy also may be considered to control tumor-related symptoms when metastatic colon cancer spreads to bone, brain, liver, and lung.

Stereotactic radiation therapy can be useful for metastatic colorectal cancer patients with liver metastases. The 1- and 2-year local control rates are about 90%, with few reports of major toxicity. This approach is a reasonable and safe alternative for patients who have fewer than four liver metastatic lesions and who are unable to undergo surgery or any other treatment options.

Systemic and Combination Therapies

The backbone of the treatment of colorectal cancer, in both the adjuvant and metastatic disease settings, is 5-fluorouracil. Although 5-fluorouracil has modest activity as a single agent, its clinical efficacy is enhanced by prolonged infusion and by coadministration with the reduced folate leucovorin. Two other cytotoxic agents commonly used to treat metastatic colorectal cancer are irinotecan (a topoisomerase I inhibitor) and oxaliplatin (a third-generation platinum analogue; see Table 164-2). Biologic agents are available to target the vascular endothelial growth factor (VEGF) signaling pathway (bevacizumab, aflibercept, and ramucirumab), the epidermal growth factor receptor (EGFR) pathway (cetuximab and panitumumab), and tyrosine kinases that are involved in cell growth, proliferation, angiogenesis, invasion, and metastasis (regorafenib).

Patients with resected stage I colon cancer have an extremely high cure rate, approaching 95%, with surgery alone, and do not need adjuvant systemic therapy (Table 179-3).[A3] For stage II patients, the risk of relapse is higher (about 25% at 3 years), and combined treatment with 5-fluorouracil and leucovorin provides modest clinical benefit.[18] However, stage II tumors that express high levels of microsatellite instability have a better prognosis than tumors with microsatellite stable disease, and survival in such patients is worse when they are treated with 5-fluorouracil. Adjuvant chemotherapy is not recommended for stage II, microsatellite instability–high disease. For high-risk stage II disease (defined by obstruction, perforation, lymphovascular invasion, perineural invasion, and fewer than 12 lymph nodes in the surgical resection specimen), the benefit from adjuvant chemotherapy is similar to that seen for stage III colon cancer. Patients with high-risk stage II disease and good performance status should receive 6 months of adjuvant therapy with combination chemotherapy that includes 5-fluorouracil, leucovorin, and oxaliplatin (FOLFOX) or an alternative combination regimen of capecitabine and oxaliplatin (XELOX/CAPOX; Table 179-3) under expert supervision, with the decision potentially guided by the presence or absence of the circulating tumor DNA.[A4] Both FOLFOX and XELOX/CAPOX significantly prolong disease-free survival and overall survival compared with fluoropyrimidine monotherapy. For patients who have comorbid illnesses and who are unable to tolerate aggressive combination chemotherapy, fluoropyrimidine monotherapy with infusional 5-fluorouracil or oral capecitabine under expert supervision is a reasonable alternative.

In patients with stage III colon cancer, 5-year disease survival rates range from 25 to 85%, depending on the number of lymph nodes that are positive in the surgical resection specimen. The usual recommendation for patients with node-positive stage III disease is to receive adjuvant systemic therapy (E-Fig. 179-1). For patients with good performance status and no comorbid illnesses, aggressive treatment with the FOLFOX regimen significantly improves long-term survival rates and represents current standard care. XELOX/CAPOX appears to be as good as FOLFOX in patients of all ages. For patients who are not candidates for aggressive cytotoxic chemotherapy, fluoropyrimidine monotherapy with either infusional 5-fluorouracil or oral capecitabine is an appropriate option. Several randomized trials show that 3 months of adjuvant therapy is as good as 6 months of therapy in lower risk patients with T1 to T3 disease and only 1 to 3 positive lymph nodes. In contrast, for stage III patients with more than 4 lymph nodes, standard 6 months of adjuvant therapy provides greater clinical benefit than 3 months of therapy, albeit at a higher cost of adverse events. CAPOX rather than FOLFOX is now viewed as a preferred option for adjuvant therapy.

TABLE 179-3 TREATMENT OF EARLY-STAGE COLON CANCER ACCORDING TO DISEASE STAGE

STAGE	SURGICAL TREATMENT	ADJUVANT CHEMOTHERAPY
I	Colectomy with en bloc removal of regional lymph nodes	Observation
II (MSI-H/dMMR)	Colectomy with en bloc removal of regional lymph nodes	Observation
II (MSS/pMMR and no high-risk features)	Colectomy with en bloc removal of regional lymph nodes	Observation *OR* Consider capecitabine (6 months) or 5-FU/leucovorin (6 months)
II (MSS/pMMR and high-risk features)	Colectomy with en bloc removal of regional lymph nodes	FOLFOX (6 months) or CAPOX (3 months) *OR* Capecitabine (6 months) or 5-FU/leucovorin (6 months) for patients who cannot tolerate aggressive chemotherapy
III (low-risk)	Colectomy with en bloc removal of regional lymph nodes	CAPOX (3 months) or FOLFOX (3-6 months) *OR* Consider capecitabine (6 months) or 5-FU/leucovorin (6 months) for patients who cannot tolerate aggressive chemotherapy
III (high-risk)	Colectomy with en bloc removal of regional lymph nodes	CAPOX (3-6 months) or FOLFOX (6 months) *OR* Consider capecitabine (6 months) or 5-FU/leucovorin (6 months) for patients who cannot tolerate aggressive chemotherapy

MSI-H/dMMR = microsatellite instability-high/defective mismatch repair; MSS-H/pMMR = microsatellite stable/proficient mismatch repair.

Rectal Adenocarcinoma

The risk of local recurrence is much greater for rectal cancer, so the therapeutic approach for patients with primary rectal adenocarcinoma is distinct from that for primary colon cancer. Rectal cancer patients require accurate preoperative staging with endoscopic rectal ultrasound or rectal MRI for precise definition of the size, extent, and depth of invasion of the rectal tumor as well as lymph node involvement. For patients with stage I rectal cancer, surgical resection is sufficient with no need for additional adjuvant treatment with either radiation or chemotherapy. However, higher-risk patients (T2 disease, T1 with poorly differentiated histology, perineural or lymphovascular invasion, or close margins) should receive postoperative pelvic irradiation with or without 5-fluorouracil chemotherapy.

Radiation therapy is considered standard therapy for patients with locally advanced stage II and III rectal adenocarcinomas to decrease local relapse rates, improve the chance of sphincter preservation, and possibly improve survival. The major issues to consider relate to timing (preoperative or postoperative) and duration (short or long), as well as whether to combine it with fluoropyrimidine-based chemotherapy. Short-course 5-day preoperative irradiation without chemotherapy, as is practiced in certain countries in Europe, may be considered when tumor downsizing is not necessary. When short-course radiation is used, postoperative systemic adjuvant therapy is recommended with either a fluoropyrimidine alone (stage II) or a fluoropyrimidine-oxaliplatin combination regimen (node-positive disease).

For locally advanced rectal cancer, which includes lymph node involvement or large bulky tumors, a 5-day course of radiotherapy followed by either 6 cycles of CAPOX or 9 cycles of FOLFOX chemotherapy, can significantly reduce 3-year disease-related treatment failure[A5] and is now considered a standard treatment. With this neoadjuvant approach, induction systemic chemotherapy is administered first and followed by chemoradiation, with the goal of downstaging the primary tumor as well as reducing the risk of distant metastatic spread. Adjuvant chemotherapy is usually administered after surgical resection.

For stage II/III disease, however, the optimal chemotherapy regimen has yet to be determined. Fluoropyrimidine monotherapy with either infusional 5-fluorouracil or oral capecitabine is usually recommended if patients have no evidence of lymph node involvement in the surgical resection specimen and if the primary tumor has been significantly downstaged. If not, however, oxaliplatin-based chemotherapy regimens with either FOLFOX or XELOX/CAPOX are usually recommended.

Metastatic Colorectal Cancer

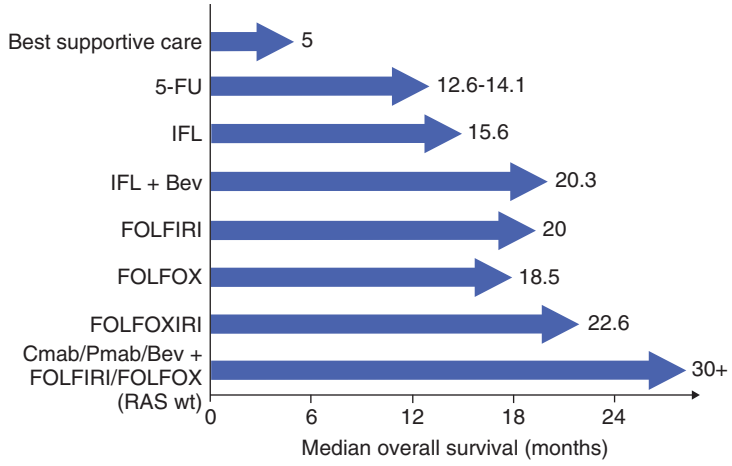
Metastatic colorectal cancer is treated with the same approach, regardless of the primary site of origin (colon versus rectum).[19,20] Metastatic colorectal cancer is becoming a chronic disease, and the key issue is to ensure that patients are treated in a continuum of care approach with exposure to all of the active agents within the therapeutic armamentarium. Current systemic cytotoxic chemotherapies in combination with various biologic agents (Chapter 29) have improved median overall survival to nearly three years (E-Fig. 179-1).[21]

First-Line Chemotherapy

For first-line treatment, the cytotoxic chemotherapy FOLFOX and FOLFIRI regimens provide virtually identical progression-free survival and overall survival,[A6] with a median overall survival of nearly 23 months. Interestingly, long-term results seem to be similar regardless of which drug (oxaliplatin or irinotecan) is combined first with 5-fluorouracil. However, the toxicity pattern varies, depending on which drug is given; irinotecan is commonly associated with GI side effects, whereas oxaliplatin treatment can lead to peripheral sensory neuropathy.

Biologic Therapy

ANTI–VASCULAR ENDOTHELIAL GROWTH FACTOR ANTIBODIES. In metastatic colorectal cancer patients with wild-type RAS, the addition of the anti-VEGF antibody bevacizumab or the anti-EGFR antibody cetuximab to cytotoxic chemotherapy (either FOLFOX or FOLFIRI) provides equivalent clinical



E-FIGURE 179-1. **Evolution of systemic therapy for metastatic colorectal cancer.** Bev = bevacizumab; Cmab = cetuximab; 5-FU = 5-flourouracil; FOLFIRI = 5-fluorouracil, folinic acid (leucovorin), irinotecan; FOLFOX = 5-fluorouracil, leucovorin, oxaliplatin; IFL = irinotecan, 5-fluorouracil, leucovorin; Pmab = panitumumab; RAS wt = RAS wild-type.

benefit, with a median progression-free survival of 10.6 months and a median overall survival of 30 months. If disease progresses, bevacizumab can be continued in combination with second-line cytotoxic chemotherapy. Aflibercept plus FOLFIRI improves survival compared with FOLFIRI alone in patients who progress despite oxaliplatin treatment. Ramucirumab is approved for use in combination with FOLFIRI in the second-line treatment of metastatic colorectal cancer. Cross-trial comparisons suggest equivalent clinical efficacy among bevacizumab, aflibercept, and ramucirumab, but aflibercept is significantly more toxic and ramucirumab is much more expensive than bevacizumab.

ANTI–EPIDERMAL GROWTH FACTOR ANTIBODIES. For epidermal growth factor receptor (EGFR) positive chemorefractory disease, two monoclonal antibodies (cetuximab and panitumumab) have nearly identical single-agent activity, and both agents can be effectively combined with FOLFIRI or FOLFOX chemotherapy in the first-line treatment setting to improve overall response rates and progression-free survival. However, these anti-EGFR antibodies should be used only in patients whose tumors express wild-type *RAS* and *BRAF*. Unfortunately, even in the setting of wild-type *RAS*, only about 30% of patients will respond to anti-EGFR therapy. Right-sided tumors derive little benefit from cetuximab, whereas left-sided tumors derive significantly greater clinical benefit from cetuximab compared with bevacizumab. Although bevacizumab is effective in both left- and right-sided tumors, its clinical efficacy is also much greater in left-sided tumors.[22]

Programmed Death 1 Blockade

Immunotherapy with an anti–programmed death 1 (PD-1) immune checkpoint inhibitor (pembrolizumab or nivolumab) is useful in patients who have metastatic disease that has progressed despite treatment with a fluoropyrimidine, oxaliplatin, and irinotecan.[23] These antibodies stimulate the T-cell immune response, thereby leading to T-cell activation and proliferation. For microsatellite instability–high or mismatch repair defective metastatic colorectal cancer,[A7] pembrolizumab is superior to 5-fluorouracil-based chemotherapy, regardless of whether patients are also receiving bevacizumab or cetuximab, with median progression-free survival doubled from 8.2 months to 16.5 months. Furthermore, patients who are treated with pembrolizumab immunotherapy have fewer treatment-related adverse events and a significantly improved health-related quality of life.[A8] The combination of nivolumab plus ipilimumab, an antibody that targets cytotoxic T-lymphocyte–associated protein 4 (CTLA4), is also associated with encouraging progression-free survival and overall survival at 12 months in patients with microsatellite instability–high or mismatch repair defective metastatic colorectal cancer, and this combination immunotherapy regimen appears to provide enhanced clinical efficacy when compared with anti-PD-1 monotherapy.[24]

BRAF *V600E Inhibition*

The 8% of patients whose metastatic cancer expresses the *BRAF* V600E mutation have an overall poor prognosis,[25] but a triplet combination of encorafenib (a *BRAF* inhibitor), cetuximab (an anti-EGFR antibody), and binimetinib (a MEK inhibitor) can improve survival compared with standard irinotecan-based chemotherapy plus cetuximab.[A9] This regimen is now considered standard of care for metastatic disease with this specific mutation.

Other Agents

Regorafenib (a multikinase inhibitor) and TAS-102 (a combination of trifluridine and tipiracil) are agents that have nearly identical clinical activity and improve median progression-free survival and overall survival in patients with progressive disease. In general, TAS-102 has a more manageable safety profile and does not require as many dose reductions or treatment delays. Sotorasib and adagrasib under expert supervision are options for solid tumors with the *KRAS*-G12C mutation.[26,27]

Locally Directed Treatment of Metastatic Disease

For select patients with metastatic colorectal cancer, complete resection of isolated hepatic or pulmonary metastases may provide long-term survival.[28] For hepatic metastasectomy, 5-year survival rates are in the 30 to 50% range. In patients initially deemed to have surgically unresectable metastatic disease, preoperative systemic therapy improves response rates. For patients with wild-type *RAS* disease, cytotoxic chemotherapy with FOLFOX or FOLFIRI in combination with cetuximab or panitumumab appears to offer the best chance for cytoreduction of the metastatic liver disease and successful surgical resection. In the setting of mutant *RAS* metastatic colorectal cancer, the anti-VEGF antibody bevacizumab combined with chemotherapy provides an objective response rate approaching 70% with successful surgical resection approaching 30%. In patients with initially unresectable *RAS* mutant colorectal liver metastases, bevacizumab combined with mFOLFOX6 can increase the resectability of liver metastases and improve survival compared with mFOLFOX6 alone.[A10] After patients have recovered from their surgical procedure, which usually requires 4 to 5 weeks, 6 months of adjuvant chemotherapy with FOLFOX is usually recommended.

Radio frequency ablation can be used for patients whose liver metastases are deemed to be surgically unresectable because of their anatomic location or because the patient is too debilitated to undergo hepatic resection. An alternative strategy is to administer fluoropyrimidine chemotherapy via the hepatic artery through an intraarterial catheter. Selective internal radiation therapy embolizes radiolabeled spheres into the hepatic artery for the treatment of liver metastases.[A11] Stereotactic body radiation therapy is also a reasonable and safe alternative for patients who have liver-limited metastatic colorectal cancer and who are unable to undergo surgery.

PREVENTION

Screening

The role of screening is to reduce colorectal cancer-related mortality by removing any precursor adenomas and by detecting true cancers at an earlier, more curable stage. For average-risk individuals, the relatively long latency between adenoma development and the development of cancer is of the order of 8 to 12 years, thereby making colorectal cancer a highly preventable disease using colonoscopy with polypectomy.[A12] For sporadic colorectal cancer, age is the major risk factor; for this reason, most patients should begin screening at age 45 years. The wide range of options for average-risk individuals (Table 179-4) can be divided into two distinct categories: stool tests for occult blood or abnormal DNA; and structural tests, which include colonoscopy, flexible sigmoidoscopy, CT colography, and double-contrast barium enema, used alone or in combination.[29] In asymptomatic adults age 50 to 69 years, one-time colonoscopy and fecal immunochemical testing are equally effective at identifying the presence of colorectal cancer, although a greater number of adenomas are identified by colonoscopy (Chapter 120). Current professional society guidelines recognize multiple screening options but recommend structural tests that can both detect and prevent colorectal cancer. For example, the American Cancer Society now recommends screening average-risk adults for colorectal cancer starting at age 45 years and high-risk individuals starting before age 40 years (or 10 years before the age when the youngest relative was diagnosed with colorectal cancer). Colonoscopy, flexible sigmoidoscopy, or a stool-based test are recommended for average-risk patients, but flexible sigmoidoscopy or colonoscopy is recommended for high-risk patients. For individuals in good health and expected to live at least more than 10 years, routine screening should continue up through age 75 years. Individuals between ages 76 to 85 years should consult with their primary health care provider as to whether screening should be continued.[30] The general recommendation is to discontinue colorectal cancer screening in individuals who are older than 85 years of age.

Patients with ulcerative colitis (Chapter 127) are 10 to 20 times more likely to develop colorectal cancer than the general population, with a 25-year cumulative incidence of about 12%. The risk is even higher in patients who have both primary sclerosing cholangitis (Chapter 141) and ulcerative colitis. If Crohn disease (Chapter 127) involves more than one-third of the colon, the risk of colorectal cancer risk is increased 6- to 8-fold. Patients with ulcerative colitis or extensive Crohn disease should have screening colonoscopy every 1 to 2 years, starting 8 to 10 years after the disease is first diagnosed. The main goal is to identify the presence of dysplasia. Multifocal low-grade dysplasia or any dysplasia that cannot be excised endoscopically is an indication for colectomy. In familial adenomatous polyposis, the *APC* gene mutation can be identified in up to 85% of affected individuals and is useful for screening.

Fecal occult blood testing detects the presence of hemoglobin from bleeding tumors. Guaiac-based testing decreases colorectal cancer mortality by 15 to 33%, with the mortality benefit persisting for 30 years. However, immunochemical-based tests have higher sensitivities and specificities than guaiac tests, and they identify 2.5-fold more advanced adenomas and colorectal cancers than do guaiac-based tests. Furthermore, they do not require any dietary restrictions and require only one stool specimen. As a result, immunochemical-based tests are now the preferred fecal occult blood test.[31] Fecal occult blood tests should be repeated on an annual basis, and any positive test should prompt colonoscopy.

TABLE 179-4 SCREENING METHODS FOR COLORECTAL CANCER*

TEST	INTERVAL
TESTS THAT DETECT ADENOMATOUS POLYPS OR CANCER	
Colonoscopy	Every 10 yr
Flexible sigmoidoscopy†	Every 5 yr
CT colography†	Every 5 yr
Double-contrast barium enema†	Every 5 yr
TESTS THAT DETECT PRIMARILY CANCER†	
Fecal occult blood tests	
• High-sensitivity guaiac-based fecal occult blood test	Annually
• Fecal immunochemical test	Annually
Stool DNA	Interval uncertain

*Beginning at age 45 for average-risk individuals.
†Positive test should prompt full colonoscopy.
CT = computed tomography.

The rationale for stool DNA tests is that both adenomas and carcinomas contain altered DNA, which is shed continuously in the stool. These stool DNA tests contain a panel designed to detect exfoliated DNA markers, including *KRAS* mutation, aberrant *NDRG4* and *BMP3* methylation, and beta-actin. Stool DNA testing identifies up to about 90% of patients with colorectal cancer and 40% of patients with advanced adenomas.[32] In a large colorectal cancer screening trial, the sensitivity of the multitarget stool DNA test for detecting colorectal cancer was 92% with stool DNA testing compared with 74% with fecal immunochemical testing, and the sensitivity for detecting advanced precancerous lesions and polyps with high-grade dysplasia was also significantly higher with stool DNA testing. However, stool DNA testing is more costly and associated with a higher false-positive rate. The optimal screening interval for stool DNA testing has not been clearly defined.

Flexible sigmoidoscopy (Chapter 120) is an endoscopic procedure that examines the rectum and distal colon up to the splenic flexure. It is performed with minimal bowel preparation, does not require sedation, and can be performed in the office by primary care doctors, nurses, or physician's assistants. This procedure detects distal cancers or polyps with the same accuracy as colonoscopy. If an adenoma is found on sigmoidoscopy, colonoscopy is required because of the high risk of synchronous polyps or cancer in the more proximal colon. Screening with flexible sigmoidoscopy (with subsequent colonoscopy as indicated) can reduce the incidence of both distal and proximal colorectal cancer by about 30%, with a significant 50% decrease in mortality from distal colorectal only. A single flexible sigmoidoscopy continues to provide significant protection against both incidental and fatal colorectal cancer for at least 15 to 17 years.[A13]

Colonoscopy (Chapter 120) allows complete visualization of the colon and removal of any visualized polyps. As such, colonoscopy is both diagnostic and preventive.[A14] Screening colonoscopy detects cancer in about 1% of patients, advanced adenoma (size >10mm, villous histology, or high-grade dysplasia) in 5 to 10% of patients, and 1 or more adenomas in at least 20% of patients. The major complication rate of screening colonoscopy is less than 3 per 1000, with more than half of such complications related to a polypectomy. After colonoscopic polypectomy, the incidence of colorectal cancer is reduced by 75 to 90%. In patients whose adenomas are detected and removed by colonoscopy, the subsequent risk of death from colorectal cancer is 50% lower than otherwise expected, with most of the benefit attributable to the removal of low-risk adenomas. The highest risk of subsequent colorectal cancer is in patients whose removed adenomas were 20 mm or greater in diameter or had high-grade dysplasia.[33] The benefit of colonoscopy is higher if it is performed by an experienced gastroenterologist. If the initial screening colonoscopy is completely normal, future screening can be deferred for 10 years. Re-screening is recommended more frequently in patients with positive findings (see Table 179-2).[34]

CT colography (virtual colonoscopy) obtains two- and three-dimensional images of the entire colon via multidetector CT scanning (Chapter 119). A rectal tube is used to infuse gas to distend the bowel for better imaging. The sensitivity is 85 to 92% for large polyps (≥10 mm), with a specificity of 83 to 89%, and about 65% for polyps 5 mm or larger. Its 96% sensitivity for detecting colorectal cancer is similar to colonoscopy. Because CT colography is less sensitive than colonoscopy for detecting lesions smaller than 10 mm and substantially less sensitive for detecting high-risk sessile serrated polyps, colonoscopy is the preferred screening procedure. Colon capsule endoscopy appears to be better than CT colography, but neither is as accurate as colonoscopy.[A15] If used, CT colography screening should begin at age 45 years and be repeated every 5 years. Discovery of a polyp larger than 5 mm requires colonoscopy.

Double-contrast barium enema (Chapter 119) can evaluate the mucosal surface of the entire colon. This test has a sensitivity of 85 to 97% for detecting colorectal cancers but only 48 to 73% for detecting large adenomas. Given this low sensitivity and the small but real risk of ionizing radiation, this imaging procedure is not recommended for routine screening.

Chemoprevention

NSAIDs[A16] and aspirin[A17,A18] reduce the formation of adenomas and inhibit the development of colon cancer by inhibiting cyclooxygenase and the subsequent generation of prostaglandin. In patients with familial adenomatous polyposis, sulindac (150 mg daily) and celecoxib can cause existing adenomas to regress and inhibit the formation of new adenomas. Aspirin also reduces the recurrence of adenomas by up to 20 to 40%, with pooled data suggesting up to a 70% reduction in the incidence of colorectal cancer when at least 75 mg of aspirin daily is taken for 5 or more years. Epidemiologic studies also show that regular users of NSAIDs have a lower risk of developing colorectal cancer. Calcium supplementation decreases the rate of metachronous adenomas by 20%, and total calcium intake greater than 1400 mg per day is associated with a significantly lower risk of colon cancer than an intake of less than 600 mg per day. Observational studies suggest that higher levels of 25-hydroxyvitamin D3 (25[OH]D) are associated with a reduced risk of colorectal cancer and also improved survival after its diagnosis. In patients with stage III colon cancer, adjuvant vitamin D supplementation is associated with a significant improvement in recurrence-free survival and overall survival. However, aspirin, NSAIDS, and calcium are not routinely recommended to prevent colorectal cancer, although they may be considered on an individual basis.

Dietary Prevention

Epidemiologic studies have identified a correlation of colorectal cancer with diets high in fat and low in fiber, green leafy vegetables, and fruits; physical inactivity; smoking; and excessive alcohol use. Increased fish consumption is associated with a lower incidence of colorectal cancer, and supplementation with the omega-3 fatty acid eicosapentaenoic acid can decrease the burden of polyps in familial adenomatous polyposis. However, randomized trials of modest dietary changes (10% less fat, 25 to 75% more fiber, 50% more fruits and vegetables) have not reduced the incidence of adenomas or colorectal cancers over 3 to 8 years of follow-up. It is possible that more prolonged dietary modification may be required to effect significant changes in the molecular events that mediate the development of adenomas and/or colorectal cancer.

PROGNOSIS

The overall prognosis for patients with colorectal cancer is mainly dependent on stage (Fig. 179-8), but up to 50% of patients who initially present with early-stage disease will recur with metastatic involvement. Five-year survival is approximately 90 to 95% for stage I disease and declines considerably to less than 10% for stage IV metastatic disease. The prognosis for stage III colorectal cancer can range from 65 to 70% for patients with only one or two lymph nodes and down to less than 25% for those with high-risk disease and more than four positive lymph nodes. Corresponding rates for rectal cancer are slightly inferior to those for colon cancer. In addition to stage, other factors that are associated with poorer outcomes in patients with early-stage colon cancer who undergo potentially curative resection include signet ring histology, high tumor grade, lymphovascular and perineural invasion, absence of host lymphoid response, evidence for obstruction or perforation preoperatively, high preoperative serum CEA levels, positive surgical margins, and microsatellite-stable disease.

Mucinous adenocarcinomas are associated with a worse overall prognosis than nonmucinous subtypes. By comparison, the medullary subtype has a relatively favorable prognosis.

Interestingly, the prognosis of colorectal cancers is not dependent on the size of the primary tumor. However, the location of the primary tumor is an important prognostic factor, with left-sided primary tumors associated with a significantly better prognosis compared with right-sided tumors. Moreover, the effect of tumor location is independent of other important clinical factors, including stage, race, and use of adjuvant chemotherapy.

Molecular biomarkers also correlate with the prognosis of all stages of colorectal cancer. *KRAS* mutations are present in 30 to 40% of colorectal cancer, and are associated with a worse prognosis. These mutations lead to constitutive

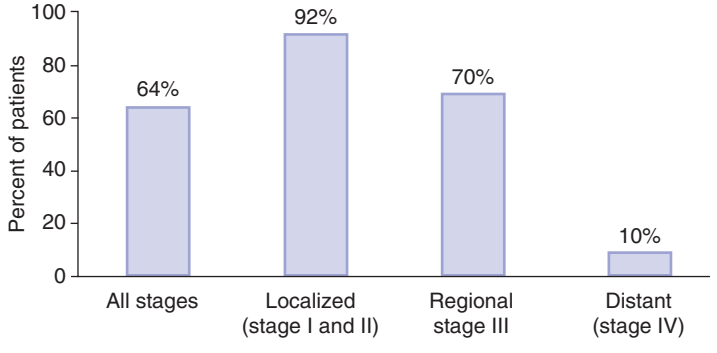


FIGURE 179-8. Five-year survival of colon cancer by disease stage.

activation of the RAS-RAF-MAPK signaling pathway downstream of EGFR, which render tumors resistant to anti-EGFR antibody therapy with cetuximab or panitumumab. *NRAS* mutations occur in only about 5% of colorectal cancer patients, and these mutations also confer resistance to anti-EGFR therapy. *BRAF* mutations, which are seen in 5 to 10% of colorectal cancer patients, are associated with poor prognosis and also predict resistance to anti-EGFR therapy.

More detailed molecular subtyping may be even more predictive. One approach groups colorectal cancers into four types—microsatellite instability immune, canonical, metabolic and mesenchymal—based on such profiling.

The poorly differentiated neuroendocrine cancers, such as true small cell carcinoma, are the most aggressive, commonly present with hepatic and other distant metastases, and have a poor overall prognosis. In contrast to carcinoids, however, poorly differentiated neuroendocrine cancers are more responsive, at least initially, to systemic chemotherapy.

180 PANCREATIC CANCER

DANIEL LAHERU

DEFINITION

More than 90% of pancreatic tumors are adenocarcinomas that arise from the ductal epithelium. Other major tumors of the pancreas include acinar cell, intraductal papillary mucinous neoplasm, mucinous cystic neoplasm, mixed histology, endocrine malignancies, carcinoid tumors, lymphomas, and a variety of rare sarcomas.

EPIDEMIOLOGY

Pancreatic ductal adenocarcinoma has one of the highest mortality-to-incidence ratios of any disease. Although it represents the tenth leading cause of cancer in the United States, it is the fourth leading cause of cancer-related deaths because most patients will die from their disease. By the year 2030, pancreatic cancer is expected to be the second leading cause of cancer-related death behind only lung cancer. Each year in the United States, approximately 50,000 individuals die from pancreatic adenocarcinoma or its complications.[1] The incidence of pancreatic cancer is slowly increasing based on the changing demographics of the U.S. population. In the United States, Blacks have a higher incidence and mortality from pancreatic cancer compared with Whites, although the incidence rate is not increasing as fast in Blacks as in Whites.[2] The risk of developing pancreatic adenocarcinoma increases with age, with a mean onset at age 71 years. The risk is equivalent in men and women, with an average lifetime risk for developing pancreatic adenocarcinoma of about 1 in 78. Globally, 70% of all pancreatic cancer cases occur in people living in advanced economies, with about 470,000 worldwide deaths in 2020.[3]

Smoking tobacco, as well as passive exposure to tobacco smoke in the environment, contributes significantly to the development of pancreatic adenocarcinoma and is also associated with a reduction in survival among patients with pancreatic cancer.[4] Occupational hazards that have been associated with an enhanced risk of developing pancreatic adenocarcinoma include exposure to chlorinated hydrocarbon solvents and heavy metals.

Most pancreatic adenocarcinoma cases are sporadic and occur without a history of the disease in first-degree relatives. Germline mutations in cancer susceptibility genes are commonly identified, even in patients without a significant family history of cancer.[5] Some pancreatic adenocarcinomas occur in association with other cancers or diseases, but most do not occur in association with a defined syndrome.

However, approximately 10% of pancreatic adenocarcinomas occur in families with a history of pancreatic adenocarcinoma.[6] In such families, the risk of developing pancreatic adenocarcinoma is increased seven-fold compared with the general population.[7] Premalignant cystic lesions of the pancreas also occur in families with pancreatic cancer. In addition to mutations of the *PALB2* gene in 3% of these families, mutations have also been identified in *ATM* or *BRCA2*, which are critical partners in the DNA damage repair pathway, as well as in *p16*.

Chronic pancreatic inflammation from alcohol misuse or genetic anomalies significantly increases the risk of being diagnosed with pancreatic adenocarcinoma. Pro-inflammatory cytokines contribute to the progression from premalignant lesion to advanced tumor.

New-onset insulin-dependent diabetes after age 50 years can be an indicator of pancreatic cancer.[8] Long-standing type 1 and type 2 diabetes mellitus may increase the risk of pancreatic adenocarcinoma. For example, the increase in obesity in the U.S. population and the concomitant increase in associated diabetes mellitus are strongly associated with an enhanced lifetime risk of developing pancreatic adenocarcinoma. Epidemiologic studies also note a relationship between type 3c diabetes (diabetes related to pancreatic disease and characterized by a severe deficiency of all glucoregulatory hormones) and the development of pancreatic adenocarcinoma. Patients with type 3c

activation of the RAS-RAF-MAPK signaling pathway downstream of EGFR, which render tumors resistant to anti-EGFR antibody therapy with cetuximab or panitumumab. *NRAS* mutations occur in only about 5% of colorectal cancer patients, and these mutations also confer resistance to anti-EGFR therapy. *BRAF* mutations, which are seen in 5 to 10% of colorectal cancer patients, are associated with poor prognosis and also predict resistance to anti-EGFR therapy.

More detailed molecular subtyping may be even more predictive. One approach groups colorectal cancers into four types—microsatellite instability immune, canonical, metabolic and mesenchymal—based on such profiling.

The poorly differentiated neuroendocrine cancers, such as true small cell carcinoma, are the most aggressive, commonly present with hepatic and other distant metastases, and have a poor overall prognosis. In contrast to carcinoids, however, poorly differentiated neuroendocrine cancers are more responsive, at least initially, to systemic chemotherapy.

180 PANCREATIC CANCER

DANIEL LAHERU

DEFINITION

More than 90% of pancreatic tumors are adenocarcinomas that arise from the ductal epithelium. Other major tumors of the pancreas include acinar cell, intraductal papillary mucinous neoplasm, mucinous cystic neoplasm, mixed histology, endocrine malignancies, carcinoid tumors, lymphomas, and a variety of rare sarcomas.

EPIDEMIOLOGY

Pancreatic ductal adenocarcinoma has one of the highest mortality-to-incidence ratios of any disease. Although it represents the tenth leading cause of cancer in the United States, it is the fourth leading cause of cancer-related deaths because most patients will die from their disease. By the year 2030, pancreatic cancer is expected to be the second leading cause of cancer-related death behind only lung cancer. Each year in the United States, approximately 50,000 individuals die from pancreatic adenocarcinoma or its complications.[1] The incidence of pancreatic cancer is slowly increasing based on the changing demographics of the U.S. population. In the United States, Blacks have a higher incidence and mortality from pancreatic cancer compared with Whites, although the incidence rate is not increasing as fast in Blacks as in Whites.[2] The risk of developing pancreatic adenocarcinoma increases with age, with a mean onset at age 71 years. The risk is equivalent in men and women, with an average lifetime risk for developing pancreatic adenocarcinoma of about 1 in 78. Globally, 70% of all pancreatic cancer cases occur in people living in advanced economies, with about 470,000 worldwide deaths in 2020.[3]

Smoking tobacco, as well as passive exposure to tobacco smoke in the environment, contributes significantly to the development of pancreatic adenocarcinoma and is also associated with a reduction in survival among patients with pancreatic cancer.[4] Occupational hazards that have been associated with an enhanced risk of developing pancreatic adenocarcinoma include exposure to chlorinated hydrocarbon solvents and heavy metals.

Most pancreatic adenocarcinoma cases are sporadic and occur without a history of the disease in first-degree relatives. Germline mutations in cancer susceptibility genes are commonly identified, even in patients without a significant family history of cancer.[5] Some pancreatic adenocarcinomas occur in association with other cancers or diseases, but most do not occur in association with a defined syndrome.

However, approximately 10% of pancreatic adenocarcinomas occur in families with a history of pancreatic adenocarcinoma.[6] In such families, the risk of developing pancreatic adenocarcinoma is increased seven-fold compared with the general population.[7] Premalignant cystic lesions of the pancreas also occur in families with pancreatic cancer. In addition to mutations of the *PALB2* gene in 3% of these families, mutations have also been identified in *ATM* or *BRCA2*, which are critical partners in the DNA damage repair pathway, as well as in *p16*.

Chronic pancreatic inflammation from alcohol misuse or genetic anomalies significantly increases the risk of being diagnosed with pancreatic adenocarcinoma. Pro-inflammatory cytokines contribute to the progression from premalignant lesion to advanced tumor.

New-onset insulin-dependent diabetes after age 50 years can be an indicator of pancreatic cancer.[8] Long-standing type 1 and type 2 diabetes mellitus may increase the risk of pancreatic adenocarcinoma. For example, the increase in obesity in the U.S. population and the concomitant increase in associated diabetes mellitus are strongly associated with an enhanced lifetime risk of developing pancreatic adenocarcinoma. Epidemiologic studies also note a relationship between type 3c diabetes (diabetes related to pancreatic disease and characterized by a severe deficiency of all glucoregulatory hormones) and the development of pancreatic adenocarcinoma. Patients with type 3c

ABSTRACT

Pancreatic cancer has one of the highest mortality-to-incidence ratios of any cancer. Risk factors for pancreatic cancer include cigarette smoking, a positive family history of pancreatic cancer, chronic pancreatitis, and diabetes mellitus (the latter having an unclear cause-and-effect relationship). The *KRAS* oncogene is mutated in more than 90% of pancreatic cancers. When a localized pancreatic cancer is suspected, a computed tomographic scan with oral and intravenous contrast and with thin cuts through the pancreas is the imaging modality of choice. Surgery followed by adjuvant chemotherapy offers the only chance to cure pancreatic cancer regardless of its stage. Neoadjuvant chemotherapy is commonly used even for patients whose disease appears to be resectable based on preoperative imaging criteria. For patients who present with metastatic cancer, chemotherapy can prolong survival.

diabetes appear to have the highest associated risk of developing pancreatic adenocarcinoma, especially in the setting of coexisting chronic pancreatitis. Type 3c diabetes is also a consequence of pancreatic adenocarcinoma in approximately 30% of patients.

PATHOBIOLOGY

Pancreatic cancer is caused by inherited (germline) and acquired (somatic) mutations in cancer-causing genes. Oncogenes and tumor suppressor genes contribute to the growth of the tumor itself as well as to the surrounding microenvironment. A major advance in understanding the development of pancreatic cancer has been the appreciation that the majority of pancreatic adenocarcinomas progress sequentially from histologically normal ductal epithelium to low-grade pancreatic intraepithelial neoplasia, to high-grade pancreatic intraepithelial neoplasia, to invasive carcinoma. This process is associated with the accumulation of specific gene alterations (Fig. 180-1).

The *KRAS* oncogene, located on chromosome 12, is the most frequently mutated oncogene in pancreatic cancer in (>90% of tumors). It encodes a membrane-bound protein that has GTP-ase activity and is involved in signal transduction. When activated by mutation, typically a point mutation in codon 12, the functions of *KRAS* are independent of growth factor control, thereby leading to chronic activation of its downstream signaling partners (*PI3K*, *MAPK*, and *RAF*), the inhibition of apoptosis, the activation of the cell cycle, migration, angiogenesis, cytoskeletal remodeling, and unchecked proliferation. *KRAS* oncogenic dose variation plays an important role in pancreatic cancer tumorigenesis, progression, and metastasis.[9]

The tumor suppressor *CDKN2A/TP16*, which is a cell cycle control gene, is commonly inactivated in pancreatic cancer, with 80 to 95% loss of activity leading to increased cell cycle progression. *TP53* is activated by DNA damage to stop cell cycle progression and repair damaged DNA or initiate apoptosis. Mutations in this tumor suppressor gene are commonly found in 50 to 75% of pancreatic tumors. Inactivation of *SMAD4* (DPC4), which is involved in regulating cell cycle progression through the transforming growth factor (TGF)-β pathway, is observed in over 50% of pancreatic cancers and is associated with worse prognosis and the development of metastases. Inactivation of *RB1* (in <10% of pancreatic cancers) and *STK11* (responsible for Peutz-Jeghers syndrome) is also observed.

Several major signaling pathways are involved in pancreatic tumorigenesis. Hedgehog (Hh) signaling, critical in embryogenesis, regulates the cell cycle and apoptosis, aids in the formation of tumor stroma, and is often upregulated and abnormal in pancreatic cancers. The NOTCH pathway, which is also important in normal embryogenesis to prevent terminal differentiation of cells until appropriate, can be abnormally activated in pancreatic cancer, thereby allowing cells to remain in an undifferentiated state that contributes to tumor growth. When the Wnt pathway is activated, β-catenin is stabilized and migrates into the nucleus, where it activates its target genes. The epidermal growth factor receptor (EGFR), TGF-β, and JAK/STAT pathways are also abnormal in pancreatic cancer cells and lead to the promotion of cell growth, proliferation, differentiation, and survival. Epigenetic modification, the process by which gene expression is altered by mechanisms other than changes in the actual DNA sequence, also has a role in pancreatic cancer tumorigenesis.[10]

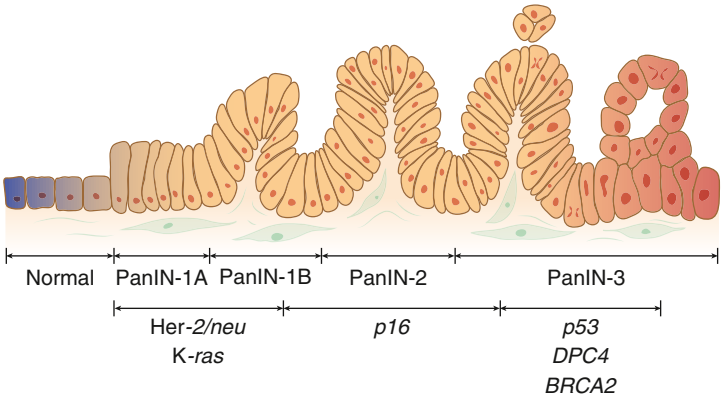

FIGURE 180-1. Genetic progression model of pancreatic adenocarcinoma. Molecular changes in the development of pancreatic ductal adenocarcinoma begin with early changes that include telomere shortening and development of mutations in *KRAS*; these are followed by loss of p16 function and expression of cyclin D1. Late changes include expression of p53 and loss of SMAD4/DPC4. PanIN = pancreatic intraepithelial neoplasia.

Shortening of telomeres and overexpression of microRNAs lead to chromosomal instability and dysregulation of gene expression, respectively.

In addition to cancer cells themselves, the tumor microenvironment is composed of stromal cells, inflammatory cells, and endothelial cells that all play a particularly important role in the growth of pancreatic cancer. Cancer cells secrete growth factors, including insulin-like growth factor (IGF)-1, fibroblast growth factor (FGF), TGF-β, vascular endothelial growth factor (VEGF), and platelet-derived growth factor (PDGF), that stimulate pancreatic stellate cells (also called myofibroblasts) to secrete excess amounts of extracellular matrix. In turn, the matrix and its stromal cells secrete cytokines and growth factors that promote the growth, invasion, and dissemination of cancer cells. This matrix also protects pancreatic cancer cells from apoptosis and generates a desmoplastic reaction that interferes with the delivery of chemotherapy to the tumor site. The local presence of TGF-β also leads to decreased activity of helper T-cells and thereby suppresses the body's immune reaction against pancreatic cancer cells.

CLINICAL MANIFESTATIONS

Many pancreatic tumors are asymptomatic when they are diagnosed by an imaging study obtained for an unrelated reason. The symptoms of early pancreatic adenocarcinoma are often subtle and include nonspecific gastrointestinal complaints (nausea, vague abdominal pain), fatigue, and weight loss of undetermined etiology. Epigastric pain and obstructive jaundice often prompt the initial diagnostic work-up of the biliary tree but are frequently late symptoms that are associated with advanced local or regionally disseminated disease. Because approximately 75% of pancreatic carcinomas are located in the head of the pancreas, clinical presentations are often related to compression or invasion of the biliary tree or pancreatic ducts. Deep or superficial venous thrombosis (Trousseau syndrome) is not infrequent, either early or late in the presentation of pancreatic adenocarcinoma. Observation of a palpably distended gallbladder (from obstruction of the distal common bile duct), or Courvoisier sign, is uncommon.

The laboratory abnormalities that accompany pancreatic adenocarcinoma at presentation include anemia and elevations of serum levels of bilirubin, alkaline phosphatase, and aminotransferases. A majority of patients eventually develop signs of obstructive jaundice as well as hyperglycemia, which reflects associated diabetes mellitus.

Early pancreatic intraepithelial neoplasia lesions are asymptomatic, and cystic lesions of the pancreas often remain asymptomatic. Some are discovered on abdominal imaging performed for other purposes, with some estimates that 2 to 15% of patients undergoing abdominal magnetic resonance imaging (MRI) may have unsuspected pancreatic cysts. Most small lesions do not cause symptoms and otherwise would remain undetected unless they later caused acute symptoms that would precipitate an abdominal computed tomographic (CT) scan. Large cysts may cause vague symptoms, but obstructive jaundice is uncommon. Most intraductal papillary mucinous neoplasms are asymptomatic, but some patients present with obstructive jaundice or with pancreatitis.

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of pancreatic adenocarcinoma includes conditions that can present as a solid pancreatic mass, including acute (or an exacerbation of chronic) pancreatitis (Chapter 130), ampullary or distal cholangiocarcinomas (Chapter 181) with associated biliary obstruction and jaundice, and nonadenocarcinomatous cystic pancreatic neoplasms.

A high proportion of incidental cysts among patients without a history of pancreatitis are neoplastic. High-resolution CT may provide a presumptive diagnosis when characteristic features are present. MRI can identify any communication between the cyst and the pancreatic duct. Endoscopic ultrasonography can differentiate benign from malignant lesions if it finds a solid mass or invasive tumor.

Cystic Neoplasms

Cystic lesions of the pancreas can be categorized into non-neoplastic (e.g., pseudocysts; see Chapter 130) and neoplastic cystic lesions.[11] Cystic neoplasms can be subcategorized into mucin-producing and non-mucin-producing cystic neoplasms.[12] Cystic neoplasms that do not produce mucin include serous cystadenomas, which do not have increased risk of cancer, papillary cystic neoplasms, and cystic pancreatic neuroendocrine tumors.

Serous cystadenomas occur more commonly in women and are nearly always benign. Though usually asymptomatic, they can be symptomatic as

they enlarge. The pathology shows a well-circumscribed fibrous capsule containing numerous small fluid-filled cysts.

Mucinous cystic neoplasms, which nearly always occur in the pancreatic body or tail in women, comprise about 50% of pancreatic tumors removed in contemporary surgical series. About one third are discovered incidentally on radiographic imaging for other purposes, but patients also may present with pain, an abdominal mass, or weight loss. A thick fibrous capsule contains cysts lined by mucin-producing duct-like cells. About 30% of mucinous cystic neoplasms have evidence of invasive adenocarcinoma with a variable prognosis.

Intraductal papillary mucinous neoplasms are mucin-producing lesions that, unlike mucinous cystic neoplasms, communicate with the main pancreatic duct. Their intraductal dysplastic epithelium resembles colorectal villous adenomas, with papillae covered by columnar epithelium and the occasional goblet cell with extensive mucin production. These neoplasms often contain at least low-grade dysplasia and are always premalignant and require follow-up.

Imaging

A computed tomographic (CT) scan with oral and intravenous contrast and thin cuts through the pancreas is the imaging procedure of choice when pancreatic adenocarcinoma is suspected. CT scans can provide information regarding the presence of metastatic disease, vascular invasion, and potential for resection. Malignancy is more common when the cyst is greater than 3 cm, has a solid component, or is associated with a dilated pancreatic duct greater than 1 cm, but malignancy is less clearly associated with the rate of growth on serial imaging studies. Consensus recommendations[13] include MRI of pancreatic cysts identified on CT imaging; endoscopic ultrasonography and fine-needle aspiration for pancreatic cysts with concerning features on MRI; and cytologic and biomarker evaluation of aspirated fluid.[14]

Endoscopic ultrasound may provide additional information for preoperative assessment, including by guiding fine-needle aspiration biopsy. However, the typical desmoplastic reaction that can encase pancreatic adenocarcinomas increases the possibility of false-negative biopsy findings. Patients with locally advanced or metastatic disease should have their diagnosis confirmed pathologically by fine-needle biopsy of the primary site or of a metastasis.

Biomarkers and Screening

Analysis of cyst fluid can correctly identify up to 90% of pancreatic cysts that would not require surgery.[15] No serum- or tumor-based biomarkers or biomarker panels are both sensitive and specific enough for accurate early detection in clinical practice, but multianalyte blood tests that can detect and localize surgically resectable cancers, including pancreatic cancers, are promising.[16] CA19.9 is the most commonly used tumor biomarker for monitoring therapeutic progress in pancreatic adenocarcinoma, but the assay lacks specificity and cannot be used for early detection. Endoscopic ultrasound is useful for the evaluation of cystic lesions and permits sampling of cystic fluid for genetic markers associated with the development of pancreatic adenocarcinoma in cancer-prone families, as well as for cytologic studies. Some data suggest a potential benefit from annual screening using MRI, magnetic resonance cholangiopancreatography, or endoscopic ultrasound in asymptomatic adults who are carriers of the high-risk *CDNK2A* mutation.

TREATMENT

Pancreatic Cysts

Patients with pancreatic cysts that have concerning features (cyst ≥ 3 cm, a dilated main pancreatic duct > 1 cm, presence of an associated solid component or clinical symptoms such as jaundice) should be referred for fine-needle aspiration guided by endoscopic ultrasound. If the cytology is consistent with either high-grade dysplasia or invasive pancreatic cancer, these patients are commonly offered surgical resection (Table 180-1).[17] In contrast, patients whose features do not warrant resection should undergo MRI surveillance every 1 to 2 years for up to 5 years.[18]

Serous cystadenomas are benign abnormalities that do not connect to pancreatic ducts and warrant surgery only if symptomatic. Mucinous cystadenomas, which are precursors of pancreatic adenocarcinoma, are overtly malignant in 15% of patients and require surgical resection. Intraductal papillary mucinous neoplasms of the pancreas may contain malignant elements in about 40% of patients particularly in patients with concerning features, and should be removed surgically.

Pancreatic Cancer

Surgical Candidates

Surgery offers the only chance to cure pancreatic cancer.[19] Tumors are considered resectable if a clear fat plane is present around the celiac and superior mesenteric arteries and if the superior mesenteric and portal veins are patent. If the superior mesenteric vein and/or the portal vein is involved, that portion of the vein must be judged to be reconstructible. After surgery, the somatostatin analogue pasireotide (900 mg subcutaneously twice daily for 7 days beginning in the morning of surgery) may reduce the risk of a fistula leak with abscess. Unfortunately, tumor will recur in the majority of patients who undergo resection, including local recurrence in approximately 40% of patients.

Adjuvant and Neoadjuvant Therapy

Decisions regarding chemotherapy should be made in a multidisciplinary manner to achieve the most timely and coordinated therapy.[20] Participation in clinical research protocols should be encouraged.

Adjuvant therapy, typically started 1 to 2 months after surgery to allow the patient to recover from the complications associated with the underlying cancer as well as from the surgery itself, is indicated under expert oversight to decrease the risk and delay the onset of locoregional and metastatic recurrence. FOLFIRINOX (oxaliplatin, irinotecan, fluorouracil, and leucovorin) is the standard of care for patients who have a good performance status,[A1] but the rate of serious side-effects (including peripheral neuropathy) is higher compared with gemcitabine. If gemcitabine is chosen, adding capecitabine can increase survival by about 10 weeks.[A2] Another option for patients with resectable pancreatic cancers is neoadjuvant FOLFIRINOX or neoadjuvant nab-paclitaxel plus gemcitabine for 3 months preoperatively followed by 3 months postoperatively.[A3,A4]

Borderline Surgical Candidates

Neoadjuvant (presurgical) therapy can downstage 15 to 40% of borderline[A5] tumors, thereby allowing patients to undergo surgery with a higher likelihood of complete resection.[21] Neoadjuvant therapy also spares some patients the risks and stress of a complex surgical procedure, because rapidly developing metastatic disease may be detected by routine restaging following the completion of neoadjuvant treatment. Unfortunately, chemotherapy-resistant cancer can be demonstrated in 15 to 35% of patients initially considered for surgery in this setting.

The use of neoadjuvant treatment also guarantees that almost all patients will receive some form of chemotherapy or chemoradiation because they do not have any postoperative complications from which to recover. The chemoradiation component of neoadjuvant therapy also decreases local recurrence rates in patients who undergo surgery.

Local Recurrence

The complications associated with local recurrence include abdominal pain, risk for bowel obstruction, gastrointestinal bleeding, and recurrent biliary obstructions. Chemoradiation versus chemotherapy alone for locally advanced pancreatic cancer can decrease the risk for local recurrence but has not improved median survival compared with chemotherapy alone.[A6]

Unresectable or Metastatic Disease

First-line therapy for unresectable or metastatic pancreatic cancer is FOLFIRINOX or gemcitabine plus nab-paclitaxel (Table 180-2).[22] Nanoliposomal irinotecan in combination with fluorouracil and folinic acid extends survival with a manageable safety profile in patients with metastatic pancreatic adenocarcinoma who previously received gemcitabine-based therapy.[A7] Gemcitabine has also been combined with targeted therapies, such as the EGFR inhibitor erlotinib, but with a very modest improvement on overall survival.[23]

In the small percentage of patients with germline mutations in *BRCA1* or *BRCA2*, olaparib (300 mg twice daily) can prolong progression-free survival by about 3.5 months in patients who have been received a platinum-containing regimen for a minimum of 4 months and have been at least stable radiographically.[A8] In patients with KRAS G12C mutations, sotorasib is a promising experimental therapy.[24]

Thromboembolism

Advanced pancreatic cancer is associated with a high risk of venous thromboembolic complications. Current guidelines do not recommend routine thromboprophylaxis for all patients with active pancreatic cancer, but this prophylaxis

TABLE 180-1 GUIDELINES FOR ASYMPTOMATIC INCIDENTAL PANCREATIC CYSTS

CYST	MANAGEMENT STRATEGY
Either (a) a solid component and dilation of the main pancreatic duct of >5 mm or (b) suspicious EUS-guided FNA	EUS-guided FNA. Surgery if high-grade dysplasia or cancer, with follow-up MRI every 2 years after surgery; if benign, no follow-up required.
Size <3 cm, no solid component, no dilation of main pancreatic duct	MRI at 1, 3, and 5 years: if changes, EUS-guided FNA; if stable at 5 years, discontinue screening.

EUS = endoscopic ultrasound; FNA = fine needle aspiration; MRI = magnetic resonance imaging.

can be considered for patients who are at high risk.[25] Thromboprophylaxis with enoxaparin (Chapter 70) is feasible and effective.[A9] Another options is rivaroxaban (see Table 70-6).[A10]

Palliative Care

Because many patients suffer from biliary obstruction, diarrhea, pain, and malnutrition, palliative care (Chapter 3) can provide great benefit. Surgery can also play an important palliative role; patients whose tumors are unresectable may experience symptomatic improvement after a biliary or gastric bypass procedure, depending on the site of obstruction. Endoscopic placement of both biliary and duodenal stents may also improve pruritus, pain, or other complications of biliary tract obstruction. Palliative care for patients with pancreatic adenocarcinoma necessitates scrupulous attention to pain management (Chapter 26), often with a multidisciplinary approach, as well as maintenance of hydration and adequate nutrition.

Prevention

Even though premalignant intraductal papillary mucinous neoplasms or pancreatic mucinous neoplasms can be detected by imaging, screening is not currently recommended in asymptomatic adults.[26] However, consensus guidelines recommend that pancreatic cancer surveillance be considered for select high-risk individuals (based on family risk or germline mutation status) and that any evaluations should be conducted in a research protocol by experienced multidisciplinary teams.[27,28]

Prognosis

Among patients with a serous cystic neoplasm followed beyond 1 year, the size increases in about 40%, is stable in about 55%, and decreases in about 5%. Serous cystadenocarcinomas develop in only about 0.1% of patients at an average follow-up of 3 years.[29]

The overall 5-year survival for all patients with pancreatic cancer is less than 5%, because the cancer is advanced when clinically detected. Once patients are diagnosed, only 15 to 20% initially have resectable and potentially curable disease. In patients with early-stage disease, median survival has improved from 20 to 24 months to 54 months with adjuvant FOLFIRINOX. Patients with locally advanced (about 25 to 30% of patients at presentation) and metastatic (about 50 to 60% of patients at presentation) disease have median survivals of 8 to 14 months and 4 to 6 months, respectively. T-cell immunity has been linked to the exceptional outcome of the few long-term survivors, and neoantigen quality has been identified as a biomarker for immunogenic tumors.

181 LIVER AND BILIARY TRACT TUMORS

ROBIN K. KELLEY AND ALAN P. VENOOK

DEFINITION

Cancers arising from the liver and biliary tract include hepatocellular carcinoma, cholangiocarcinoma, and gallbladder adenocarcinoma, as well as other less common malignant histologies (E-Table 181-1, Fig. 181-1). Cholangiocarcinomas are further subclassified by their anatomic location along the biliary tract: intrahepatic (also known as peripheral) or extrahepatic, which includes hilar (also known as Klatskin tumors) and distal locations. These cancers collectively represent the third leading cause of cancer death worldwide and are rising in incidence.

The liver is also a frequent site of metastasis from other primary cancers. The diagnosis of liver tumors must distinguish metastatic disease from primary liver tumors.

EPIDEMIOLOGY

Hepatocellular Carcinoma

Hepatocellular carcinoma is the most common primary tumor of the liver and the third leading cause of cancer death worldwide.[1] It accounts for approximately 900,000 new cases and 830,000 deaths each year. More than 80% of hepatocellular carcinomas occur in developing countries (Fig. 181-2), owing to an increased prevalence of risk factors, particularly hepatitis B virus and hepatitis C virus (Chapter 134), but rates are also increasing in developed nations (E-Table 181-2).[2] Hepatitis B and hepatitis C viruses together account

181 LIVER AND BILIARY TRACT TUMORS

ROBIN K. KELLEY AND ALAN P. VENOOK

DEFINITION

Cancers arising from the liver and biliary tract include hepatocellular carcinoma, cholangiocarcinoma, and gallbladder adenocarcinoma, as well as other less common malignant histologies (E-Table 181-1, Fig. 181-1). Cholangiocarcinomas are further subclassified by their anatomic location along the biliary tract: intrahepatic (also known as peripheral) or extrahepatic, which includes hilar (also known as Klatskin tumors) and distal locations. These cancers collectively represent the third leading cause of cancer death worldwide and are rising in incidence.

The liver is also a frequent site of metastasis from other primary cancers. The diagnosis of liver tumors must distinguish metastatic disease from primary liver tumors.

EPIDEMIOLOGY

Hepatocellular Carcinoma

Hepatocellular carcinoma is the most common primary tumor of the liver and the third leading cause of cancer death worldwide.[1] It accounts for approximately 900,000 new cases and 830,000 deaths each year. More than 80% of hepatocellular carcinomas occur in developing countries (Fig. 181-2), owing to an increased prevalence of risk factors, particularly hepatitis B virus and hepatitis C virus (Chapter 134), but rates are also increasing in developed nations (E-Table 181-2).[2] Hepatitis B and hepatitis C viruses together account

ABSTRACT

Malignancies arising from the liver parenchyma and biliary ductal epithelium are a heterogeneous group of cancers with generally poor prognosis. Risk factors include chronic liver injury from conditions such as viral hepatitis, alcohol, and nonalcoholic fatty liver disease, though some cases are idiopathic. These cancers collectively represent the third leading cause of cancer death worldwide and are rising in incidence. Hepatocellular carcinoma, the most common primary liver cancer that arises from the liver parenchyma, may be curable by surgery or transplantation if diagnosed at early stages. More advanced stages are treated with liver-directed therapies, such as chemoembolization, with systemic immunotherapy in combination with antiangiogenic therapy, or with multikinase inhibitors, (e.g., sorafenib, lenvatinib, regorafenib, and cabozantinib), all of which can prolong survival. Immunotherapy with the checkpoint inhibitors pembrolizumab or nivolumab alone or in combination with ipilimumab can provide durable tumor response.

Cholangiocarcinomas and gall bladder carcinomas arise from the biliary tract. These tumors, which are often complicated by biliary obstruction and infection, require multidisciplinary management. If diagnosed at early stages, biliary cancers sometimes can be cured by surgical approaches, but the risk of recurrence is high. Advanced or unresectable biliary cancers are treated with chemotherapy, with the combination of gemcitabine plus cisplatin as a standard first line regimen. Molecularly targeted therapies can benefit cholangiocarcinomas that harbor activating *FGFR2* translocations or mutations in *IDH1* or *BRAF*.

E-TABLE 181-1 PRIMARY MALIGNANT TUMORS OF THE LIVER AND BILIARY TRACT

TUMOR TYPE	APPROXIMATE ANNUAL INCIDENCE
Hepatocellular carcinoma	900,000 cases/yr worldwide*
Gallbladder carcinoma	220,000 cases/yr worldwide
Cholangiocarcinoma	10,000 cases/yr in United States†
Mixed hepatocellular-cholangiocarcinoma	Rare
Fibrolamellar hepatocellular carcinoma	Rare
Cystadenocarcinoma	Rare
Hepatic endothelioid hemangioendothelioma	Rare
Angiosarcoma and other sarcomas	Rare

*Includes cases of intrahepatic cholangiocarcinoma.
†Includes cases of gallbladder cancer and excludes cases of intrahepatic cholangiocarcinoma.

E-TABLE 181-2 RISK FACTORS FOR HEPATOCELLULAR CARCINOMA

RISK FACTOR	INCIDENCE OF HEPATOCELLULAR CARCINOMA*
Asian male HBV carriers over age 40	0.4-0.6%/yr
Asian female HBV carriers over age 50	0.3-0.6%/yr
HBV carrier with family history of HCC	Higher incidence than without family history
African/North American Blacks with HBV	HCC occurs at younger age
HBV carriers with cirrhosis	3-8%/yr
HCV cirrhosis	3-5%/yr
Stage 4 primary biliary cirrhosis	3-5%/yr
Hereditary hemochromatosis with cirrhosis	Unknown
α_1-Antitrypsin deficiency with cirrhosis	Unknown
Other-cause cirrhosis	Unknown

for more than 80% of all hepatocellular carcinomas worldwide. Alcoholic cirrhosis is another classic predisposing factor.[3] However, nonalcoholic fatty liver disease has surpassed both viral hepatitis and alcoholic cirrhosis as the leading cause of hepatocellular carcinomas in the United States.[4]

Nonalcoholic fatty liver disease can lead to steatohepatitis, cirrhosis, and hepatocellular carcinoma.[5] When hepatocellular carcinoma develops in patients with nonalcoholic liver disease without preceding cirrhosis, it is more likely to present at an older age, with a larger tumor burden, and with higher rates of recurrent tumor compared with tumors that develop after patients already have cirrhosis.[6]

Hepatitis B virus is endemic in regions such as Asia and sub-Saharan Africa, and it can be vertically transmitted from mother to fetus in utero. Hepatitis C virus, which may be acquired by intravenous drug use or from blood transfusion (Chapter 134), is another important risk factor for hepatocellular carcinoma. In patients who have cirrhosis caused by hepatitis C virus, the estimated annual risk for developing hepatocellular carcinoma is 3 to 5% per year. Other risk factors for hepatocellular carcinoma include hepatitis D virus (which requires coinfection with hepatitis B virus to be pathogenic), hereditary hemochromatosis (Chapter 196), α_1-antitrypsin deficiency (Chapter 132), primary biliary cirrhosis (Chapter 141), autoimmune hepatitis (Chapter 135), male gender, and dietary exposure to fungal aflatoxins.

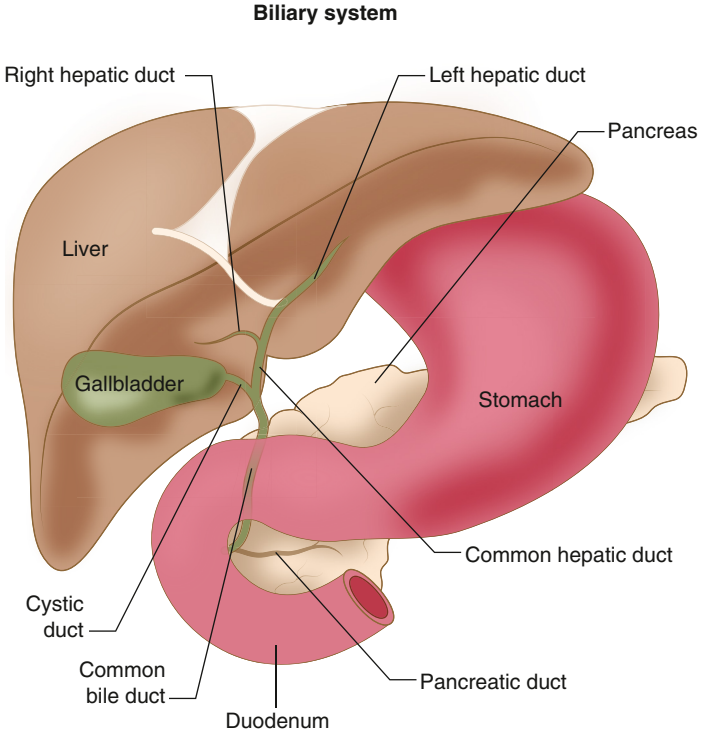

FIGURE 181-1. Anatomy of the liver and biliary tract. Hepatocellular carcinoma arises from liver parenchyma, and cholangiocarcinomas arise from the biliary ductal epithelium within (intrahepatic or peripheral) or outside of (extrahepatic) the liver. Tumors arising from the confluence of the right and left bile duct at the hepatic hilum are called hilar cholangiocarcinoma or Klatskin tumors.

Biliary Tract Cancers

Cholangiocarcinoma is the most common primary biliary tract malignancy and the second most common primary cancer of the liver after hepatocellular carcinoma. The incidence of intrahepatic cholangiocarcinoma appears to be increasing. Although most cases are sporadic, the risk for cholangiocarcinoma is increased in patients who have primary sclerosing cholangitis (Chapter 141), inflammatory bowel disease (Chapter 127), viral hepatitis (Chapter 135), congenital choledochal cysts or other structural abnormalities of the biliary tract, chronic pancreatitis (Chapter 130), obesity (Chapter 201), fluke infections (Chapter 326) and other causes of chronic cholangitis, bile duct adenomas, Caroli disease, and diabetes mellitus (Chapter 210).

Gallbladder adenocarcinomas are rare in the United States[7] but account for about 220,000 cases per year worldwide. The incidence varies geographically, with higher incidence rates reported in India and areas of South America and Asia. Risk factors for gallbladder adenocarcinoma include female gender, chronic cholelithiasis, chronic cholecystitis, history of gallbladder polyps, and abnormalities of the common bile duct (Chapter 141). Calcification of the gallbladder ("porcelain gallbladder") is often considered a risk factor, but it is only weakly associated with the development of cancer.

Other Primary Liver Cancers

Other primary tumors of the liver are much less common, with poorly understood risk factors. Chronic inflammatory conditions, including viral hepatitis, may be associated with the development of combined-histology liver tumors. Exposure to polyvinyl chloride has been implicated in the development of hepatic angiosarcomas. The fibrolamellar variant of hepatocellular carcinoma

may occur more commonly in females. Hepatoblastoma tumors occur in infants and children, but almost never in adults.

PATHOBIOLOGY

Hepatocellular Carcinoma

Hepatocellular carcinoma is an epithelial neoplasm that arises from malignant transformation of liver hepatocytes (Fig. 181-3A and B). In the majority of cases, the pathogenesis of hepatocellular carcinoma is thought to be a multistep process triggered by underlying liver injury (such as from viral hepatitis, steatohepatitis, alcohol, iron overload, or exposure to aflatoxin). Subsequent inflammation, necrosis, regeneration, cell turnover, and proliferation[8] result in the progressive accumulation of genetic damage and somatic (acquired) mutations. Activation of oncogenes or inactivation of tumor suppressor genes, dysplasia, and subsequently carcinoma can arise. Promoter mutations that result in activation of the *TERT* gene, which encodes telomerase reverse transcriptase, are seen in approximately 45% of cases, inactivation of the tumor suppressor *TP53* is seen in about 30% of cases, and activation of the oncogene β-catenin (*CTNNB1*) gene is seen in about 25% of cases. Alterations in *Wnt*, cell cycle, and chromatin-remodeling pathways also have been described.

In hepatitis B-associated hepatocellular carcinoma, a unique mechanism of malignant transformation is direct integration of viral DNA into the host genome. This integration appears to favor specific loci, including activation of the *TERT* gene promoter.

Biliary Tract Cancers

Cholangiocarcinomas are a histologically diverse group of epithelial cancers that may arise from multiple different liver cell types, including biliary epithelial cells or hepatic progenitor cells, and are often surrounded by a dense stroma with cancer-associated fibroblasts (see Fig. 181-3C). Cholangiocarcinomas are associated with underlying inflammation and cholestasis, which activate growth factors and a proliferative response. Overexpression of *Notch1* and *AKT* has been implicated in a process by which hepatocytes are converted into the cholangiocytic precursors of intrahepatic cholangiocarcinoma. Molecular and genomic subtypes of biliary tract cancers can also be defined by mutational status and gene expression profiles.[9] For example, isocitrate dehydrogenase-1 (*IDH1*) gene mutations and fibroblast growth factor receptor-2 (*FGFR2*) gene fusions each occur in approximately 15% of intrahepatic cholangiocarcinomas.

CLINICAL MANIFESTATIONS

General Considerations

Liver masses, regardless of their cause, can be asymptomatic and may be detected during evaluation of abnormal liver chemistry tests (Chapter 133) or an imaging procedure obtained for an unrelated issue. In patients with known cirrhosis or other risk factors for hepatocellular carcinoma (see E-Table 181-2), an asymptomatic liver tumor also may be identified by surveillance imaging and/or monitoring of the serum alpha-fetoprotein (AFP) level.

Regardless of their histologic subtype, primary tumors of the liver can manifest with right upper quadrant pain, mass effect causing early satiety or obstructive symptoms, nausea, bleeding, and biliary obstruction. All of these tumors have metastatic potential, so they also can less commonly present with constitutional symptoms (e.g., weight loss, fevers, or night sweats) or signs or symptoms of metastatic disease (e.g., bone pain or a pathologic fracture). Paraneoplastic syndromes are rare in hepatobiliary cancers but can include the hypercalcemia of malignancy as well as erythrocytosis from the production of erythropoietin by tumor (Chapter 164).[10]

Hepatocellular Carcinoma

The clinical presentation of hepatocellular carcinoma can vary according to the extent of tumor and the degree of underlying liver dysfunction. Some patients may be asymptomatic, particularly when diagnosed by surveillance imaging and/or by an elevation in the AFP level. In cases with hepatic decompensation triggered by a growing tumor, patients present with symptoms of worsening liver function and portal hypertension (Chapter 139), including new ascites, encephalopathy, gastrointestinal bleeding, or jaundice, especially in the presence of associated portal vein thrombosis. In other cases, tumor involvement of the sensitive liver capsule can cause chronic progressive upper abdominal pain. The sudden onset acute pain suggests bleeding into the tumor or rupture. Constitutional symptoms such as cachexia, fatigue, and weight loss may be present with advanced stages.

On physical examination, patients with hepatocellular carcinoma may have an enlarged liver with tenderness, and a palpable mass lead to the diagnosis of hepatocellular carcinoma. A bruit may be auscultated over the liver surface, particularly with large and rapidly growing tumors. Ascites, jaundice, signs of portal hypertension (e.g., caput medusae and splenomegaly), and asterixis may be variably present if hepatic function has decompensated. The AFP level is elevated in approximately 70% of cases but is not diagnostic.

Biliary Tract Cancers

Extrahepatic cholangiocarcinomas most often manifest with signs and symptoms of biliary obstruction, such as jaundice, pruritus, pale stools, dark urine, anorexia, nausea, and weight loss. Intrahepatic cholangiocarcinomas can also cause obstruction, but generally only when extensive disease is present. Less commonly, complications such as biliary fistulas and hemobilia can occur.

Gallbladder cancers are often diagnosed incidentally during cholecystectomy, but some cases can be associated with right upper quadrant pain, biliary colic, or a tender and palpable mass. Biliary obstruction can lead to infections of the biliary tract (cholangitis), with symptoms including right upper quadrant pain, fever, chills, nausea, vomiting, and jaundice (Chapter 141). Cholangitis can lead to complications such bacteremia (most commonly with gram-negative enteric pathogens), sepsis, and abscess formation.

DIAGNOSIS

General Considerations

The approach to patients with a liver mass requires assessment of risk factors and extent of any underlying liver disease. The diagnostic evaluation, staging, and treatment options are guided by whether underlying liver disease is present as well as by its extent. The differential diagnosis for hepatocellular carcinoma and biliary tract cancers includes benign liver lesions (such as hemangiomas, adenomas, abscesses, and regenerative nodules), malignant tumors of other primary liver histologies, mixed-histology tumors, and metastatic disease.

Hepatocellular Carcinoma

Whether the patient has an asymptomatic liver mass or has a mass discovered because of symptoms, it must be evaluated promptly (see Fig. 132-6). Hepatocellular carcinoma is unique in oncology in that a diagnosis can be made radiographically without tumor tissue sampling in the appropriate clinical

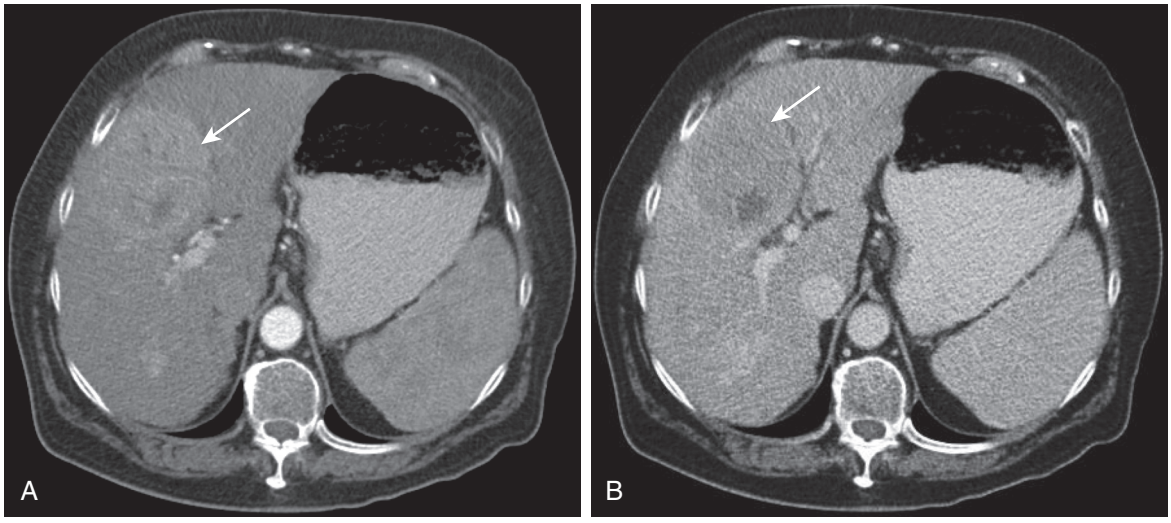

FIGURE 181-4. Imaging of hepatocellular carcinoma. In this contrast-enhanced computed tomography scan of the liver of a patient with hepatocellular carcinoma, a tumor in the right hepatic lobe demonstrates arterial phase enhancement (*arrow*, **A**) followed by "wash-out" in the portal venous phase (*arrow*, **B**). The bright arterial enhancement of hepatocellular carcinoma lesions on contrast-enhanced imaging studies is due to the propensity of this tumor to parasitize blood supply from the hepatic artery, whereas the normal hepatic parenchyma derives the majority of its blood supply from the portal vein.

context.[11] For the diagnostic evaluation of liver tumors, either magnetic resonance imaging (MRI) or computed tomography (CT) with multiple phases of contrast administration (including arterial, portal venous, and delayed phases) is recommended. In patients with risk factors for hepatocellular carcinoma (see E-Table 181-2), a nodule of at least 1 cm featuring arterial phase enhancement with decreased enhancement during the portal venous phase of contrast (known as "washout") is sufficient for a radiographic diagnosis (Fig. 181-4A and B).

A biopsy is warranted to confirm the diagnosis of hepatocellular carcinoma if diagnostic imaging criteria are not met. Because of the rare risk of seeding tumor along the needle track, biopsy should be performed at an expert center. When the first biopsy is inconclusive in patients whose liver nodules were found during the follow-up for chronic liver disease (e.g., fibrosis or no definitive focal lesion), a second biopsy of a suspicious lesion is indicated because its yield is as high as for the first biopsy.[12] An elevated AFP level is not sufficiently sensitive or specific for the diagnosis of hepatocellular carcinoma in cirrhotic patients with a liver mass.

Once a patient has been radiographically and/or pathologically diagnosed with hepatocellular carcinoma, the staging for extent of disease requires cross-sectional imaging of the chest, abdomen, and pelvis; an AFP measurement; and a bone scan if symptoms or signs of bone metastases (such as bone pain or markedly elevated alkaline phosphatase value) are present. Staging of hepatocellular carcinoma also requires a thorough assessment of underlying liver function, which affects prognosis and treatment options independent of the extent of the tumor.

Biliary Tract Cancers

For the diagnosis of biliary tract cancers, endoluminal approaches, such as by endoscopic retrograde cholangiopancreatography (ERCP) cytologic brushing or endoscopic ultrasound fine-needle aspiration, are preferred in patients whose early-stage disease may be amenable to curative surgery or transplantation. Cholangiography (by ERCP or magnetic resonance cholangiogram) may be indicated for both diagnostic and therapeutic purposes (such as stent placement), particularly if biliary obstruction is present. Staging of biliary tract and other rarer types of liver cancer generally includes cross-sectional imaging of the chest, abdomen, and pelvis. A mass in the gallbladder fossa suggests primary gallbladder cancer. Unlike hepatocellular carcinoma, cholangiocarcinomas characteristically display progressive enhancement during the portal venous phase of contrast imaging (Fig. 181-5). Biliary obstruction and ipsilateral hepatic lobe atrophy and contralateral hypertrophy may be present and can sometimes obscure identification of the actual tumor mass.

For biliary tract cancers, CA-19-9 and carcinoembryonic antigen (CEA) tumor markers may be elevated and can help to monitor response to treatment, although levels can be confounded if biliary obstruction and hyperbilirubinemia are present. Upper and lower endoscopy are indicated to exclude metastatic disease in patients who are diagnosed with likely intrahepatic cholangiocarcinoma, which otherwise can be difficult to discriminate from metastatic disease radiographically and histologically. Diagnostic laparoscopy should be considered to exclude peritoneal disease before undertaking a laparotomy for curative resection in patients with newly diagnosed gallbladder adenocarcinoma and cholangiocarcinoma because imaging may not detect peritoneal metastases, which would affect surgical decision making.

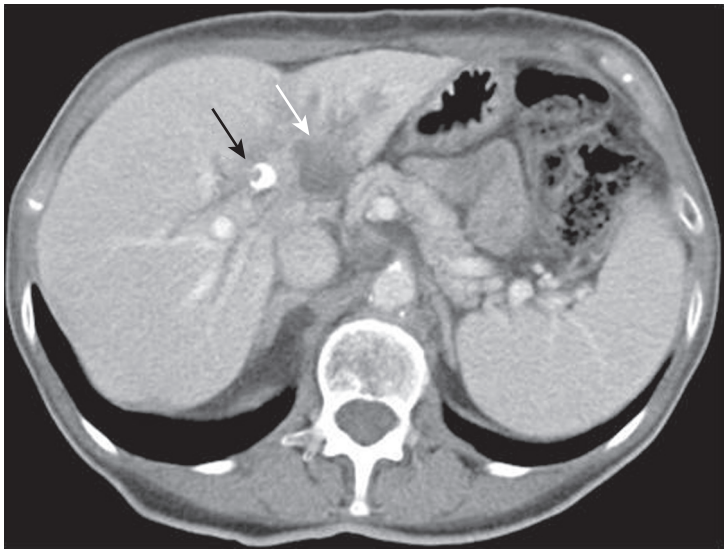

FIGURE 181-5. Imaging of cholangiocarcinoma. This computerized tomography image with contrast in portal venous phase depicts an infiltrative hilar cholangiocarcinoma (Klatskin tumor) extending into the left hepatic lobe (*white arrow*) with an endobiliary stent in place (*black arrow*).

TREATMENT

General Considerations

The treatment of patients with hepatobiliary cancers requires management of underlying liver disease or obstruction as well as the tumor itself. In patients with active hepatitis B virus infection or prior exposure, close monitoring of liver function and viral load is advisable; antiviral therapy (Chapter 135) may be required to prevent reactivation, which can occur with immunosuppressive therapy (Chapter 29). Management of liver tumors in patients with cirrhosis may necessitate treatment for complications of portal hypertension or liver dysfunction (Chapter 139). In patients with biliary tract cancers, biliary obstruction (Chapter 141) is a common complication that often requires endoscopic stent placement, percutaneous drainage, or antibiotic therapy if cholangitis develops. The doses of chemotherapy agents and of medications used for supportive care may require adjustment depending on the degree of liver dysfunction.

Hepatocellular Carcinoma

Surgery and Ablation

The treatment of early stages of hepatocellular carcinoma depends on the degree of liver dysfunction.[13] In patients who have localized hepatocellular carcinoma and preserved liver function without significant portal hypertension, surgical resection can be curative, with 5-year survival rates of approximately 60 to 80% in carefully selected patients. Among patients who have increasing degrees of portal hypertension, however, surgical outcomes are significantly poorer. For individuals with contraindications to surgery or inadequate projected future function of the liver remnant, ablation of small tumors (by radiofrequency, microwaves, or ethanol injection) can provide long-term control and is sometimes curative. Adjuvant systemic therapy does not improve outcomes after surgery or ablation for hepatocellular carcinoma.

If patients have one lesion 5 cm or smaller or up to three lesions 3 cm or smaller each without any evidence of vascular involvement or extrahepatic spread, and are not candidates for resection because of the tumor's location or inadequate hepatic reserve, orthotopic liver transplantation (Chapter 140) can provide long-term survival similar to that of patients undergoing transplantation for cirrhosis without cancer. Patients who have larger tumors may be accepted for transplantation at selected centers, often accompanied by liver-directed treatments such as embolization or ablation to control the tumor burden while awaiting transplant.

Embolization

When the hepatocellular carcinoma tumor burden exceeds criteria for transplantation or surgery but remains limited to the liver, liver-directed therapies can delay progression and prolong survival but are not likely to be curative. Transarterial chemoembolization, which delivers embolic material usually mixed with chemotherapeutic agents[A1] via arterial catheters directly to vascular tumors within the liver (Fig. 181-6), can prolong survival in patients who have intermediate-stage hepatocellular carcinoma. Radioembolization using yttrium-90 bound to glass or resin microspheres is another option.

Systemic Therapy for Advanced Disease

For patients with more advanced stage hepatocellular carcinoma, conventional cytotoxic chemotherapy agents do not improve survival. The combination of atezolizumab (a programmed death [PD]-L1 immune checkpoint inhibitor) and bevacizumab (a VEGF inhibitor) under expert supervision significantly improves progression-free survival, overall survival, and quality of life compared with sorafenib,[A2] which was the prior standard of care. As a result, it has become the standard of care for advanced hepatocellular carcinoma in patients with Child-Turcotte-Pugh A liver function (see Table 139-2).[14] Sorafenib also can significantly prolong survival, but tumors shrink in fewer than 5% of patients. Lenvatinib (a multikinase inhibitor that targets VEGFR and fibroblast growth factor receptors) is not inferior to sorafenib.[A3] The addition of other targeted therapies or chemotherapy to sorafenib has not improved outcomes over sorafenib monotherapy.

After progression on first-line therapy, the multikinase inhibitors regorafenib and cabozantinib improve survival compared with placebo.[A4,A5] The vascular endothelial growth factor receptor 2 inhibitor, ramucirumab, alco can improve survival in patients who have an elevated alpha-fetoprotein tumor marker greater than 400 ng/mL.[A6]

Monotherapy with either pembrolizumab and nivolumab can provide a durable objective tumor response in 15 to 20% of patients but has not improved overall survival.[15] The combination of nivolumab plus the ipilimumab can achieve objective responses in over 30% of patients,[16] but its impact on survival has not been established.

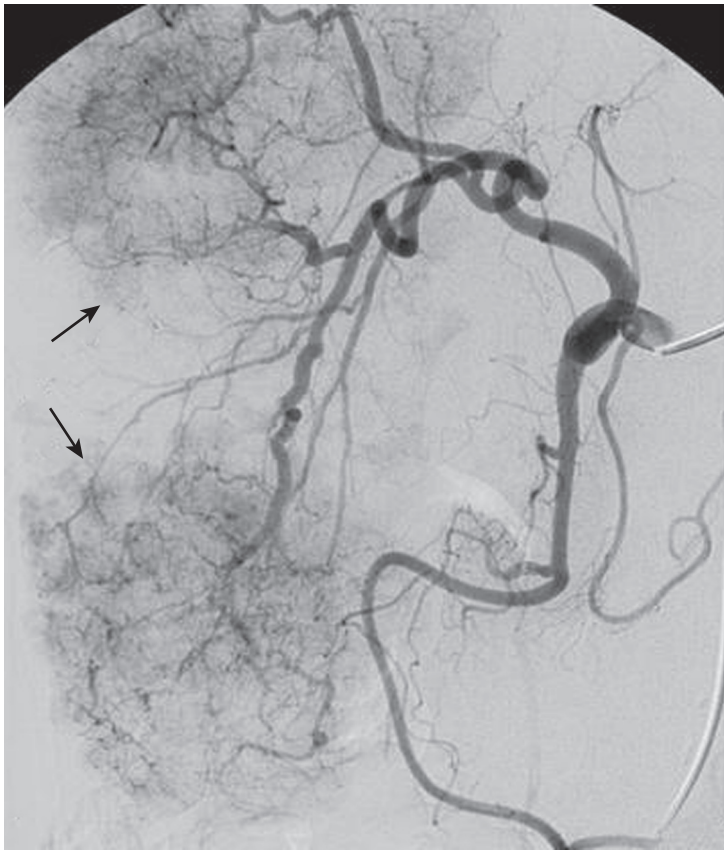

FIGURE 181-6. Transarterial chemoembolization of hepatocellular carcinoma. This common hepatic artery angiogram from a 42-year-old woman with hepatitis B shows two distinct areas of "tumor blush" corresponding to underlying hepatocellular carcinoma lesions (*arrows*) that were treated by transarterial chemoembolization. (Courtesy Dr. Nicholas Fidelman, Department of Interventional Radiology, University of California, San Francisco.)

Biliary Tract Cancers

Surgery

Surgical resection is the definitive therapy for patients with localized biliary tract cancers,[17,18] including gallbladder cancer.[19] For patients with distal cholangiocarcinoma, a Whipple pancreaticoduodenectomy may be required. Liver transplantation for early-stage hilar cholangiocarcinoma after neoadjuvant chemotherapy and/or chemoradiation may be an option at certain centers in highly selected patients.

For gallbladder cancer, cholecystectomy with en bloc hepatic resection and porta hepatis lymphadenectomy is recommended for patients with a gallbladder mass identified preoperatively on imaging or intraoperatively. A staging laparoscopy may be performed in advance to exclude occult peritoneal carcinomatosis. For patients with early-stage gallbladder cancer diagnosed incidentally on review of surgical pathologic findings after a cholecystectomy performed for benign causes, patients with tumors invading no deeper than the lamina propria (T1a) and negative surgical margins may be treated with observation only. If tumor invasion extends to the muscular layer (T1b) or beyond, patients should be referred to a specialized center for consideration of additional hepatic resection and lymphadenectomy.

Other Therapies

For patients with cholangiocarcinoma and gallbladder cancers, adjuvant chemotherapy, radiation, or chemoradiation can improve survival rates after surgical resection.[20] For example, the addition of adjuvant capecitabine for 6 months significantly prolongs overall survival and recurrence-free survival following resection of cholangiocarcinoma or gallbladder cancer and has become a standard adjuvant option.[A7]

In patients with advanced biliary tract cancers not amenable to resection, the addition of the immune checkpoint inhibitor durvalumab to combination chemotherapy (gemcitabine plus cisplatin) improves survival compared with chemotherapy alone.[A8] After progression on gemcitabine plus cisplatin chemotherapy, the combination of 5-fluorouracil plus oxaliplatin (FOLFOX) can improve survival compared with supportive care.[A9] Genomically targeted therapies, including *IDH1* and *FGRFR2* inhibitors, have shown benefit for mutation-defined subsets. For example, the IDH1 inhibitor ivosidenib improves progression-free survival in patients whose cholangiocarcinomas harbor *IDH1* mutations.[A10] The FGFR inhibitors pemigatinib and infigratinib can provide durable responses in patients whose cholangiocarcinomas are positive for *FGRF2* fusion.[21] For the rare subset of patients whose cholangiocarcinomas are mismatch repair (MMR) pathway–deficient, pembrolizumab can provide durable responses and prolongs survival.[22]

End-of-Life Care

Palliative care and end-of-life care (Chapter 3) play an integral role in management of patients who have primary hepatobiliary cancers because most patients progress and succumb to their cancer or to complications within a relatively short period of time. Palliative care specialists and social workers provide important ancillary services in the end-of-life care for patients with hepatobiliary cancers. Referral to hospice care (Chapter 3) may be appropriate when patients have progressed on standard anticancer therapies and/or are ineligible for further anticancer therapy because of extent of disease, liver dysfunction, poor performance status, or patient preferences.

As with most advanced cancers, pain control (Chapter 26), treatment of nausea (see Table 118-5) and constipation (see Table 122-3), and family and social support are essential. Pain management in patients with prior or active substance abuse disorder (Chapter 365) may be complicated by tolerance and/or dependency. In some cases, patients and caregivers may require providers' reassurance before using opiates or other analgesics for pain control because of

concerns about addiction. Bone metastases may require palliative radiation or stabilization procedures. Patients with advanced stages of hepatobiliary cancers, particularly hepatocellular carcinoma, are also at risk for developing complications of end-stage liver disease, such as intractable ascites, jaundice, pruritus, encephalopathy, infections, and gastrointestinal bleeding (Chapter 121). Diuretic therapy, therapeutic paracentesis, and endoscopic management of gastrointestinal bleeding may be required. In biliary tract cancers, biliary obstruction and recurrent cholangitis also may require endoscopic or percutaneous biliary drainage (Chapter 141)[23] and antibiotic therapy for palliation.

In the United States, hepatocellular carcinoma is associated with a high incidence of health disparities (Chapter 4) related to immigrant status, being a member of racial or ethnic minority, and lower socioeconomic status. Clinicians must have an awareness of cross-cultural issues surrounding disclosure of diagnosis, pain control, use of alternative therapies, and end-of-life care.

PREVENTION

Screening and surveillance for hepatocellular carcinoma is associated with improved outcomes in selected populations with cirrhosis,[24] but routine screening and surveillance remains controversial even for high-risk populations. Hepatitis B virus vaccination and treatment programs (Chapters 134 and 135) can reduce the incidence of hepatocellular carcinoma. Treatment of chronic hepatitis C infection my reduce the risk of hepatocellular cancer by about one-third, but the risk still appears to be perhaps 20-fold higher than in the general population. Prevention and treatment of alcohol-related disorders, obesity, and other conditions associated with nonalcoholic fatty liver disease are appropriate measures to mitigate risk factors and to minimize ongoing liver injury, but prospective evidence regarding any reduction in the risk of cancer is limited. Some data suggest that low-dose aspirin can significantly lower the risk of hepatocellular carcinoma and liver-related mortality in patients with chronic viral hepatitis.[25]

Limited evidence to support preventive measures or screening for biliary tract cancers. Patients who have primary sclerosing cholangitis (Chapter 141) are at increased risk for cholangiocarcinoma. Periodic screening by noninvasive imaging and serum CA-19-9 marker measurements may be considered, but supporting data are limited.

PROGNOSIS

The prognosis of patients with hepatocellular carcinoma and biliary tract cancers is generally poor. For patients with hepatocellular carcinoma or intrahepatic cholangiocarcinoma, the overall 5-year survival rate across stages is approximately 20%. Hepatocellular carcinomas associated with steatohepatitis and alcoholic liver disease have a similar clinical course, even though the characteristic features underlying these two diseases are different.

For the minority of patients whose hepatocellular carcinomas or intrahepatic cholangiocarcinomas are diagnosed at a localized stage of disease, the 5-year relative survival rate approaches 30%, but 5-year cause-specific survival rates generally approximate or exceed 60% when patients with early stages of disease undergo curative ablation, surgery, or transplantation. For patients who are diagnosed with metastatic hepatocellular carcinoma or cholangiocarcinoma, the 5-year survival rate is less than 5%, and the median overall survival is less than 1 year.

For patients with gallbladder adenocarcinoma, the overall 5-year survival rate ranges from approximately 50% for patients who have stage I tumors to less than 5% for patients who have metastatic disease. The rate of metastatic recurrence is high even among patients who have resectable gallbladder carcinoma. The prognosis of patients with rarer types of primary liver cancers such as fibrolamellar hepatocellular carcinoma, hepatic endothelioid hemangioendothelioma, or hepatic angiosarcoma is highly variable.

182 TUMORS OF THE KIDNEY, BLADDER, URETERS, AND RENAL PELVIS

DEAN F. BAJORIN

RENAL CELL CARCINOMA

DEFINITION

Cancers of the kidney are a heterogeneous group of neoplasms, the majority of which are of epithelial origin and malignant. Renal cell carcinoma, classically referred to as clear cell carcinoma or hypernephroma, is not a single malignancy. Rather, renal cell carcinoma comprises a group of distinguishable entities (Table 182-1), each with a strong relationship between its morphologic and genetic features.[1] The metastatic potential depends on the histologic subtype and ranges from the most virulent conventional clear cell carcinomas (65% of total tumors but accounting for 90% of the metastases), to the more indolent papillary and chromophobe carcinomas (25% of the total but only 10% of the metastases), and to the benign oncocytomas (10% of all tumors).

EPIDEMIOLOGY

Over 75,000 new tumors of the kidney and renal pelvis are diagnosed in the United States annually, and they result in approximately 14,000 deaths each year. These cancers represent the sixth most common form of cancer in men and the ninth most common in women. The increase in incidence of renal cell cancers may be in part related to early detection as a consequence of computed tomography (CT) and magnetic resonance imaging (MRI) of the abdomen for other medical conditions. The ratio of males to females is approximately 2 : 1 to 3 : 1, and the incidence is highest in Black Americans and lowest in Asians and Pacific Islanders. The mean age at diagnosis is in the sixth to seventh decade of life. Aside from genetic predisposition, risk factors associated with renal cell carcinoma include cigarette smoking, obesity, hypertension, and the use of diuretics.[2] Obese persons have an increased risk for renal cell carcinoma, and the risk rises with increasing body mass index. The elevated risk associated with diuretic use is difficult to distinguish from the increased risk associated with hypertension. Renal cell carcinoma is more prevalent in patients with pre-existing renal injury,[3] such as polycystic kidney disease (Chapter 112), horseshoe kidney (Chapter 113), and chronic renal failure requiring hemodialysis (Chapters 116 and 117).

PATHOBIOLOGY

Renal Cell Carcinoma

Clear cell renal cell carcinoma constitutes approximately 65% of renal tumors (Table 182-2) and is believed to be derived from the proximal convoluted tubule. It is generally solitary and well circumscribed, with a golden yellow color that results from the abundant cytoplasmic lipid. Higher-grade tumors

concerns about addiction. Bone metastases may require palliative radiation or stabilization procedures. Patients with advanced stages of hepatobiliary cancers, particularly hepatocellular carcinoma, are also at risk for developing complications of end-stage liver disease, such as intractable ascites, jaundice, pruritus, encephalopathy, infections, and gastrointestinal bleeding (Chapter 121). Diuretic therapy, therapeutic paracentesis, and endoscopic management of gastrointestinal bleeding may be required. In biliary tract cancers, biliary obstruction and recurrent cholangitis also may require endoscopic or percutaneous biliary drainage (Chapter 141)[23] and antibiotic therapy for palliation.

In the United States, hepatocellular carcinoma is associated with a high incidence of health disparities (Chapter 4) related to immigrant status, being a member of racial or ethnic minority, and lower socioeconomic status. Clinicians must have an awareness of cross-cultural issues surrounding disclosure of diagnosis, pain control, use of alternative therapies, and end-of-life care.

PREVENTION

Screening and surveillance for hepatocellular carcinoma is associated with improved outcomes in selected populations with cirrhosis,[24] but routine screening and surveillance remains controversial even for high-risk populations. Hepatitis B virus vaccination and treatment programs (Chapters 134 and 135) can reduce the incidence of hepatocellular carcinoma. Treatment of chronic hepatitis C infection my reduce the risk of hepatocellular cancer by about one-third, but the risk still appears to be perhaps 20-fold higher than in the general population. Prevention and treatment of alcohol-related disorders, obesity, and other conditions associated with nonalcoholic fatty liver disease are appropriate measures to mitigate risk factors and to minimize ongoing liver injury, but prospective evidence regarding any reduction in the risk of cancer is limited. Some data suggest that low-dose aspirin can significantly lower the risk of hepatocellular carcinoma and liver-related mortality in patients with chronic viral hepatitis.[25]

Limited evidence to support preventive measures or screening for biliary tract cancers. Patients who have primary sclerosing cholangitis (Chapter 141) are at increased risk for cholangiocarcinoma. Periodic screening by noninvasive imaging and serum CA-19-9 marker measurements may be considered, but supporting data are limited.

PROGNOSIS

The prognosis of patients with hepatocellular carcinoma and biliary tract cancers is generally poor. For patients with hepatocellular carcinoma or intrahepatic cholangiocarcinoma, the overall 5-year survival rate across stages is approximately 20%. Hepatocellular carcinomas associated with steatohepatitis and alcoholic liver disease have a similar clinical course, even though the characteristic features underlying these two diseases are different.

For the minority of patients whose hepatocellular carcinomas or intrahepatic cholangiocarcinomas are diagnosed at a localized stage of disease, the 5-year relative survival rate approaches 30%, but 5-year cause-specific survival rates generally approximate or exceed 60% when patients with early stages of disease undergo curative ablation, surgery, or transplantation. For patients who are diagnosed with metastatic hepatocellular carcinoma or cholangiocarcinoma, the 5-year survival rate is less than 5%, and the median overall survival is less than 1 year.

For patients with gallbladder adenocarcinoma, the overall 5-year survival rate ranges from approximately 50% for patients who have stage I tumors to less than 5% for patients who have metastatic disease. The rate of metastatic recurrence is high even among patients who have resectable gallbladder carcinoma. The prognosis of patients with rarer types of primary liver cancers such as fibrolamellar hepatocellular carcinoma, hepatic endothelioid hemangioendothelioma, or hepatic angiosarcoma is highly variable.

182 TUMORS OF THE KIDNEY, BLADDER, URETERS, AND RENAL PELVIS

DEAN F. BAJORIN

RENAL CELL CARCINOMA

DEFINITION

Cancers of the kidney are a heterogeneous group of neoplasms, the majority of which are of epithelial origin and malignant. Renal cell carcinoma, classically referred to as clear cell carcinoma or hypernephroma, is not a single malignancy. Rather, renal cell carcinoma comprises a group of distinguishable entities (Table 182-1), each with a strong relationship between its morphologic and genetic features.[1] The metastatic potential depends on the histologic subtype and ranges from the most virulent conventional clear cell carcinomas (65% of total tumors but accounting for 90% of the metastases), to the more indolent papillary and chromophobe carcinomas (25% of the total but only 10% of the metastases), and to the benign oncocytomas (10% of all tumors).

EPIDEMIOLOGY

Over 75,000 new tumors of the kidney and renal pelvis are diagnosed in the United States annually, and they result in approximately 14,000 deaths each year. These cancers represent the sixth most common form of cancer in men and the ninth most common in women. The increase in incidence of renal cell cancers may be in part related to early detection as a consequence of computed tomography (CT) and magnetic resonance imaging (MRI) of the abdomen for other medical conditions. The ratio of males to females is approximately 2 : 1 to 3 : 1, and the incidence is highest in Black Americans and lowest in Asians and Pacific Islanders. The mean age at diagnosis is in the sixth to seventh decade of life. Aside from genetic predisposition, risk factors associated with renal cell carcinoma include cigarette smoking, obesity, hypertension, and the use of diuretics.[2] Obese persons have an increased risk for renal cell carcinoma, and the risk rises with increasing body mass index. The elevated risk associated with diuretic use is difficult to distinguish from the increased risk associated with hypertension. Renal cell carcinoma is more prevalent in patients with pre-existing renal injury,[3] such as polycystic kidney disease (Chapter 112), horseshoe kidney (Chapter 113), and chronic renal failure requiring hemodialysis (Chapters 116 and 117).

PATHOBIOLOGY

Renal Cell Carcinoma

Clear cell renal cell carcinoma constitutes approximately 65% of renal tumors (Table 182-2) and is believed to be derived from the proximal convoluted tubule. It is generally solitary and well circumscribed, with a golden yellow color that results from the abundant cytoplasmic lipid. Higher-grade tumors

ABSTRACT

Cancers of the kidney, ureters, and bladder include a broad spectrum of cancers with marked differences in etiology, cell of origin, surgical management, systemic therapy, and clinical outcomes. Clear cell cancer is the most common tumor that arises in the kidney. Urothelial cancer is the most common malignancy arising in the bladder, renal pelvis, ureters, and urethra. All stage 1 renal and urothelial cancers are characterized by very favorable cure rates when managed by either surgery alone or, in the case of bladder cancer, additional medications instilled directly in the bladder. Organ preservation approaches have been used in selected cases of both primary kidney and bladder cancers, either by partial nephrectomy for kidney cancer or trimodality therapy consisting of cystoscopic resection, radiation, and chemotherapy for bladder tumors. The management of stage 2 and 3 renal cell and urothelial cancer frequently includes both surgery and systemic treatment, such as adjuvant immunotherapy or tyrosine kinase inhibitor treatment for kidney cancer and either neoadjuvant or adjuvant chemotherapy or immunotherapy for urothelial cancers of the bladder, ureter, and renal pelvis. Systemic treatment with immunotherapy and tyrosine kinase inhibitors improves the clinical outcomes of patients with stage 4 kidney cancer and can sometimes achieve long-term cures. Multiagent chemotherapy and immunotherapy using checkpoint blockade inhibitors, both of which have demonstrated potential curability of metastatic disease, are standard treatments for urothelial cancers.

TABLE 182-1 CLASSIFICATION OF RENAL CELL TUMORS ACCORDING TO THE 2016 WHO CLASSIFICATION

CURRENT RENAL CELL TUMOR SUBTYPES
Clear cell (conventional) renal cell carcinoma* (65-70%)
Papillary (chromophil) renal cell carcinoma* (15-20%)
Chromophobe renal cell carcinoma* (5-7%)
Collecting duct carcinoma*
Renal medullary carcinoma*
Mucinous tubular and spindle cell carcinoma*
RCC, unclassified*
Oncocytoma
Papillary (chromophil) adenoma
NEW RENAL CELL TUMOR SUBTYPES
Multilocular cystic renal neoplasm of low malignant potential
Mi T family translocation renal cell carcinoma*
Tubulocystic renal cell carcinoma*
Acquired cystic disease–associated renal cell carcinoma*
Clear cell papillary renal cell carcinoma*
Succinate dehydrogenase–deficient renal cell carcinoma*
Hereditary leiomyomatosis and associated renal cell carcinoma*

*Malignant.

Tumor subtypes comprising the percentages of all renal cell carcinomas (in parentheses), respectively.

Mi T = microphthalmia transcription factor; WHO = World Health Organization.

Adapted from Inamura K. Renal cell tumors: understanding their molecular pathological epidemiology and the 2016 WHO classification. *Int J Mol Sci*. 2017;18:2195. The revised 2016 WHO classification added the new tumor subtypes to the 2013 International Society of Urological Pathology (ISUP) Vancouver Classification of Renal Neoplasia (Srigley JR, Delahunt B, Eble JN, et al. *Am J Surg Pathol*. 2013;37:1469-1489).

TABLE 182-2 HISTOLOGIC SUBTYPES, GENETICS, AND SYNDROMES

HISTOLOGIC SUBTYPE	PERCENT	MAJOR GENETIC/ MOLECULAR DEFECTS	ASSOCIATED SYNDROMES
Conventional clear cell	75	LOH 3p mutation of 3p26 (*VHL*)	Von Hippel-Lindau hereditary renal cell carcinoma (RCC)
Papillary 1	5	*MET* gene mutation 7q34	Hereditary papillary renal cell carcinoma (HPRCC)
Papillary 2	10	Fumarate hydratase (*FH*)1q42.1	Hereditary leiomyomatosis renal cell carcinoma (HLRCC)
Chromophobe	5	Birt-Hogg Dubé 17p11.2 (*FLCN*)	Birt-Hogg Dubé
Oncocytoma	9.7	Birt-Hogg Dubé 17p11.2 (*FLCN*)	Familial oncocytoma Birt-Hogg Dubé
Collecting duct	0.4	−18, −Y	Renal medullary carcinoma

Modified from Zambrano N. Histopathology and molecular genetics of renal tumors. *J Urol*. 1999;162:1246-1258.

contain less lipid and glycogen. Approximately 50% of the tumors exhibit either a solid or acinar growth pattern that is characterized by solid sheets of tumor cells accompanied by a rich capillary vascular network.

Clear cell renal cell carcinoma is characterized by the loss of genetic material from the short arm of chromosome 3 (3p) and mutations in the von Hippel-Lindau (*VHL*) gene.[4] In patients with von Hippel-Lindau disease (Chapter 385), these losses and mutations occur in virtually all cases. The more common sporadic tumors also have somatic mutations and hypermethylation in the same region in approximately 75 to 80% of cases. Conventional clear cell tumors have a mutation in the *VHL* gene, which is inactivated by a point mutation or by epigenetic gene silencing by promoter methylation. The loss of *VHL*, which is responsible for ubiquination and degradation of the hypoxia-inducible factor (HIF), leads to upregulation of HIF-responsive genes responsible for angiogenesis and cell growth. Two of these upregulated genes are platelet-derived growth factor (PDGF) and vascular endothelial growth factor (VEGF), which are pro-angiogenic proteins that are thought to induce the neovascularity in both primary and metastatic clear cell cancers. Patients with von Hippel-Lindau disease more commonly develop tumors at an earlier age and frequently have multiple tumors. Other tumors associated with the syndrome include central nervous system hemangioblastomas, pancreatic neuroendocrine tumors, pheochromocytomas, retinal angiomas, and epididymal cystadenomas (Chapter 385). Molecular characterization of renal cell carcinoma shows alterations in genes responsible for maintenance of chromatin states such as *PBRM1*, the SWI/SNF chromatin remodeling complex including *ARID1A* and *SMARCA4*, and members of the P13K/AKT pathway.

Papillary Renal Cell Carcinomas

Papillary renal cell carcinomas comprise from 7 to 14% of primary epithelial renal neoplasms. The majority of patients present with unilateral tumors. Multifocality, either bilateral or multifocal lesions in the same kidney, is present in approximately 45% of cases. The majority of these tumors exhibit a broad morphologic spectrum, including papillary, papillary-trabecular, and papillary-solid areas; associated necrosis is a common finding. The classic papillary pattern is characterized by discrete papillary fronds lined by neoplastic epithelial cells and containing a central fibrovascular core, easily recognized on low magnification.

The majority of sporadic papillary renal cell carcinomas are characterized by trisomy of chromosomes 7 and 17 and loss of chromosome Y. Chromophobe renal cell cancers have genetic loss on chromosomes 1 and Y, as well as combined chromosomal losses affecting chromosomes 1, 6, 10, 13, 17, and 21. Hereditary papillary renal cell cancer is a result of germline mutations and activation of the *MET* proto-oncogene, which is located on chromosome 7q. These cells have aberrant hepatocyte growth factor receptors that are unable to deactivate after binding by the growth factor. Somatic *MET* gene amplifications also are observed in approximately 10% of cases of sporadic papillary renal cancer.[5]

These tumors are divided into type 1 and type 2 lesions, based on cytologic features and genetic differences. Comprehensive molecular characterization shows that type 1 and type 2 papillary renal cell carcinomas are clinically and biologically distinct.

Chromophobe Renal Cell Cancer

Chromophobe renal cancers account for 6 to 11% of renal epithelial tumors. Characteristically, these tumors are solitary and discrete but not encapsulated. The typical histologic findings consist of large round-to-polygonal cells with well-defined cell borders and pale basophilic cytoplasm admixed with a smaller population of polygonal cells with eosinophilic cytoplasm. These tumors may be quite large at diagnosis, with resectable tumors reported as big as 23 cm.

Other Renal Tumors

Hereditary leiomyomatosis renal cell carcinoma, which is characterized by alteration of the gene fumarate hydratase, is associated with uterine leiomyomas (more common) or leiomyosarcoma (rare), cutaneous nodules (leiomyomas), and type 2 papillary renal cell carcinoma, which is often solitary and frequently develops metastases. Birt-Hogg-Dubé syndrome is a rare disorder predominantly associated with chromophobe renal cancers but in which clear cell and chromophobe/oncocytic tumors can develop. Birt-Hogg-Dubé syndrome is characterized by fibrofolliculomas, pulmonary cysts, pneumothorax, and bilateral renal tumors. The gene associated with Birt-Hogg-Dubé syndrome has been mapped to 17p and expresses a novel protein, folliculin, whose function is not yet fully characterized.

CLINICAL MANIFESTATIONS

The majority of patients are asymptomatic at presentation, with about 50% of tumors detected by an abdominal ultrasound, a CT scan, or an MRI obtained for unrelated medical reasons. The next most common presentation is with asymptomatic hematuria, often microscopic. The classic presenting triad of hematuria, a palpable mass, and pain is now unusual, and less than 5% of patients have a palpable mass at presentation. The more common manifesting symptoms are anemia, weight loss, malaise, and anorexia (Table 182-3). Patients who present with renal cell carcinoma frequently have associated paraneoplastic syndromes (Chapter 164).[6] Hypercalcemia (Chapter 227) is observed in approximately 20% of patients and can be due to the secretion of parathyroid hormone, parathyroid hormone–like peptide, and interleukin-6 (IL-6), which stimulate osteoclastic bone resorption. Other associated syndromes include hypertension, erythrocytosis (from ectopic erythropoietin production), and the rare Stauffer syndrome, which is liver dysfunction without hepatic metastases and which resolves after surgical resection of the tumor.

TABLE 182-3 PRESENTING SYMPTOMS AND SIGNS OF RENAL CELL CARCINOMA (BOTH LOCALIZED AND METASTATIC DISEASE)

SYMPTOMS AND SIGNS	PERCENT
Anemia	52
Hepatic dysfunction	32
Weight loss	23
Hypoalbuminemia	20
Malaise	19
Hypercalcemia	13
Anorexia	11
Thrombocytosis	9
Night sweats	8
Fever	8
Hypertension	3
Erythrocytosis	4
Chills	3

DIAGNOSIS

Ultrasonography, CT, and MRI can help distinguish benign from malignant lesions. Ultrasound can distinguish small simple cysts from solid lesions. For other renal cystic lesions, CT or MRI can define three categories: likely benign lesions that require no follow-up; lesions that are usually benign (generally smooth wall of no more than 3 mm with enhancing septa) but require repeat imaging at 6 months, 12 months, and then annually for 5 years; or thicker-walled or irregularly enhancing lesions that require biopsy.

CT is the most reliable method for evaluating solid lesions.[7] The preferred CT scan for renal masses can be divided into four phases, including the precontrast images, the arterial phase (~25 seconds after injection), the nephrographic phase (~90 seconds into the injection), and the excretory phase. The most important phases for imaging renal tumors are the precontrast and nephrographic images because renal lesions appear low in density in contrast to the uniformly enhanced renal parenchyma. The arterial phase is helpful for identifying renal arteries and small hypervascular masses. The excretory phase aids in assessing the collecting system and the renal pelvis. Lack of enhancement is consistent with a hemorrhagic or inflammatory cyst that can mimic a solid lesion. Macroscopic fat in a solid renal mass suggests an angiomyolipoma.

The complete evaluation for patients with suspected renal cell carcinoma should include a complete blood count, a chemistry profile, and a CT scan of the chest, abdomen, and pelvis. CT scan is also helpful for detecting regional metastases and for indicating when partial nephrectomy is feasible. MRI is useful for imaging tumors in patients who have poor renal function and in whom intravenous contrast may be contraindicated. MRI is also helpful for delineating any thrombi that may be extending into the renal vein or inferior vena cava, and magnetic resonance angiography can determine the number and location of renal arteries in patients who are candidates for partial nephrectomy. Once the evaluation is complete, the clinical stage is assessed using the Tumor, Node, Metastasis (TNM) system (Table 182-4). A bone scan is indicated for patients with clinically advanced disease, hypercalcemia, bone pain, and/or an elevated alkaline phosphatase level.

TABLE 182-4 TNM STAGING OF RENAL CELL CARCINOMA

TUMOR, NODE, AND METASTASIS CLINICAL CLASSIFICATION	
T—Primary Tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 7 cm or less in greatest dimension, limited to the kidney
T1a	Tumor 4.0 cm or less in greatest dimension, limited to the kidney
T1b	Tumor more than 4 cm but not more than 7 cm in greatest dimension, limited to the kidney
T2	Tumor more than 7 cm in greatest dimension, limited to the kidney
T2a	Tumor more than 7 cm but less than or equal to 10 cm in greatest dimension, limited to the kidney
T2b	Tumor more than 10 cm, limited to the kidney
T3	Tumor extends into major veins or the perinephric tissues or into the ipsilateral adrenal gland and but not beyond the Gerota fascia
T3a	Tumor extends into renal vein or its segmental branches or pelvicalyceal system, or invades perirenal and/or renal sinus fat but not beyond the Gerota fascia
T3b	Tumor extends into the vena cava below the diaphragm
T3c	Tumor extends into the vena cava above the diaphragm or invades the wall of the vena cava
T4	Tumor invades beyond the Gerota fascia (including contiguous extension into the ipsilateral adrenal gland)
N—Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in regional lymph node(s)
M—Distant Metastasis	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
STAGE GROUPING	
Stage I	T1 N0 M0
Stage II	T2 N0 M0
Stage III	T1 N1 M0
	T2 N1 M0
	T3a N0 or N1 M0
	T3b N0 or N1 M0
	T3c N0 or N1 M0
Stage IV	T4 N0 M0
	T4 N1 M0
	Any T Any N M1

TREATMENT

Renal Cell Carcinoma

Localized Disease

The increasing prevalence of small tumors discovered incidentally on imaging has resulted in a marked increase in the use of partial nephrectomy rather than complete nephrectomy. For tumors of 7 cm or less, partial nephrectomy by the open or minimally invasive laparoscopic technique provides local tumor control and survival similar to radical nephrectomy. Partial nephrectomy preserves some renal function and reduces the risk for renal insufficiency over time. Partial nephrectomy is further supported by the fact that approximately 35% of renal cortical tumors are indolent papillary or chromophobe carcinomas.

Radical nephrectomy is generally preferred for large and centrally localized tumors that have effectively replaced the majority of the normal renal parenchyma, tumors associated with regional adenopathy (of benign or malignant etiology), tumors that extend into the inferior vena cava or right atrial vein, and even when metastatic disease is evident.[8] Radical nephrectomy can be performed laparoscopically or by an open technique through a flank, transperitoneal, or transthoracic approach. The ipsilateral adrenal gland is also removed, but a regional lymph node dissection is optional and controversial.

Renal cell carcinomas are resistant to both radiation therapy and cytotoxic chemotherapy, so neither modality is useful for adjuvant therapy after nephrectomy. However, sunitinib (a tyrosine kinase inhibitor that targets vascular endothelial growth factor [VEGF])[A1] and pembrolizumab (an antibody that inhibits programmed death-1 [PD-1] receptors)[A2] under expert oversight are effective as adjunctive treatment in patients at high risk for recurrence after nephrectomy.

Metastatic Disease

Surgery

Approximately 30% of patients with renal cell carcinoma present with metastatic disease, usually with pain from either an unresectable primary tumor or skeletal metastases, and an additional 20 to 30% of patients with surgically resected primary tumors will relapse with metastases.[9] Radiation therapy is

frequently used for palliation of bone metastases and for patients with multiple brain metastases. Palliative nephrectomy is sometimes used to provide symptomatic relief of pain. In other patients, surgical resection of the primary tumor can be considered, even in the presence of metastatic disease,[A3] but this approach is now less common with the advent of more effective systemic therapies. However, resection of metastatic sites of disease (metastasectomy) may extend survival in selected patients and may even cure a subset of patients.[10] The patients most likely to benefit from surgical resection of metastatic disease have a disease-free interval of greater than 1 year after nephrectomy, a solitary site of metastasis, and lung metastases.

Medications

Current consensus recommendations[11] are to use anti–PD-1 antibodies (nivolumab, pembrolizumab, or avelumab) in combination with either tyrosine kinase inhibitor therapy (e.g., axitinib, cabozantinib, lenvatinib, and sorafenib) or anti-CTLA antibodies (e.g., ipilumimab) under expert supervision for first-line treatment of metastatic clear cell carcinoma. Nivolumab in combination with either cabozantinib[A4] or ipilumimab[A5] provides significantly better progression-free and overall survival compared with sunitinib monotherapy, except perhaps for patients who have favorable risk factors. Pembrolizumab in combination with a tyrosine kinase inhibitor, either lenvatinib[A6] or axitinib,[A7,A8] is also superior to sunitinib monotherapy in terms of both progression-free and overall survival. Pembrolizumab plus either axitinib or lenvatinib is recommended in all patients irrespective of risk, whereas nivolumab plus ipilumimb is recommended in patients with intermediate and poor risk features. Common side effects with tyrosine kinase inhibitors include fatigue, diarrhea, hypertension, and hand-foot syndrome (a condition in which blisters appear at sites of physical contact).

Two drugs targeting the mammalian target of rapamycin (mTOR) pathway, everolimus and temsirolimus, are effective for the treatment of renal cell carcinoma. Everolimus, an oral mTOR inhibitor, is used most frequently based on clinical benefit in patients who have been previously treated with sunitinib or sorafenib. Belzutifan (a small molecule inhibitor of hypoxia-inducible factor-2) is useful for patients who have cancers associated with *VHL* mutations. Side effects include anemia, hypoxia, fatigue, increased glucose, headache, and nausea; both the anemia and the hypoxia can be severe.

Non–Clear Cell Cancer

For non–clear cell renal carcinoma, evidence supports sunitinib under expert supervision as the recommended treatment.[A9] Cabozantinib, as a single agent or in combination with immune therapy, is another potential agent.

PREVENTION

No interventions are proven to prevent renal cancers. However, the risk may decrease by 20 or so years after smoking cessation. Avoiding obesity also may decrease the risk. Whether controlling hypertension will reduce the risk is uncertain.

PROGNOSIS

Progression-free survival and overall survival rates for resected nonmetastatic renal cortical tumors substantially differ according to multiple factors, including age, size, grade, and pathologic state. Overall, 5-year survival rates are 90 to 95% for localized disease, 70% for disease with regional spread, and only 15% for disease with distant spread. Of the more common histologic subtypes of renal cell carcinoma, the prognosis of clear cell renal cell carcinoma is less favorable than that of papillary renal cell carcinoma; chromophobe renal cell carcinoma is the most favorable.

In patients with metastatic disease, clinical features associated with poorer natural history include low performance status, a hemoglobin concentration below 12 g/dL, an albumin-corrected calcium level above 10.2 mg/dL, an absolute neutrophil count above 7000/μL, a platelet count above 400,000/μL, and absence of prior nephrectomy. Survival directly correlates with the number of these pretreatment risk factors. For example, in patients who are treated with modern combination therapy, 85% of patients with zero risk factors survive for 30 months compared with about 70% for one risk factor, 60% for two risk factors, 40% for three risk factors, and 30% for four to six factors.[12] In patients who have solitary metastases after otherwise successful surgical therapy, long-term survival is seen after metastasectomy in the lung (up to 45%) and even in the brain (up to 20%) lesion.

BLADDER CANCER

DEFINITION

A spectrum of tumors arises from the urothelial lining of the bladder, renal pelvis, ureters, and urethra. The vast majority of tumors originate in the bladder, with a minority originating in the upper tracts (renal pelvis and ureters) and even fewer from the proximal urethra. Transitional cell carcinoma is the most common histologic type. Although transitional cell cancers possess a variable natural history, they have a proclivity for multifocality, high recurrence rates, and progression to higher pathologic stages. These tumors are generally grouped into the three broad categories of non–muscle-invasive, muscle-invasive, and metastatic disease, each of which differs in clinical behavior, prognosis, and primary management. For non–muscle-invasive tumors, the aim is to prevent recurrences and progression to a more advanced stage. In muscle-invasive disease, the medical challenge is to integrate the modalities of surgery, chemotherapy, and/or radiation to optimize cure and minimize morbidity. For metastatic disease, chemotherapy is used to palliate the symptoms of most patients, but there is a subset of patients for whom combination chemotherapy may result in long-term cure. Long-term cure is directly related to stage and grade, ranging from 99% for low-grade Ta tumors to up to 15% for metastatic disease.

EPIDEMIOLOGY

An estimated 80,000 or so new cases of bladder cancer are diagnosed in the United States annually, and approximately 17,000 patients die from this disease each year. The overall 77% 5-year survival rate for all stages results in a prevalence of more than 500,000 people living with bladder cancer in the United States. The ratio of males to females is 3:1, and bladder cancer is the fourth most common cancer in men. It is estimated that men have a 1 in 27 chance of developing this cancer in their lifetimes, whereas the risk is 1 in 89 for women. Bladder cancer is twice as prevalent in Whites as in Black Americans and is less frequently observed in Asians. The vast majority of patients (90%) are over age 50 years at diagnosis, with a median age of 73 years.
